Pelvic organ defects occur as compartmental defects of vaginal support. Patients may have any combination of compartmental defects, and multiple defects are very common. **The aims of surgical management include restoration of normal vaginal anatomy while maintaining and potentially restoring visceral and sexual function.** It is critical to understand the patient's goals and expectations of treatment to ensure that the prescribed treatment will meet these goals. This is the art of tailoring the appropriate treatment for each individual surgical patient.

SURGICAL ANATOMY OF THE PELVIC FLOOR

Anatomy

Supporting Structures

Bony Scaffolding. The bones of the pelvis provide the scaffold on which the soft-tissue supports (muscles, ligaments, and fascia) are anchored. It consists of paired innominate bones on both sides of the sacrum. These three bones comprise the pelvic girdle. The innominate bones are further divided into the ilium, the ischium, and the pubis. The ischial spine provides attachment for the arcus tendineus fasciae pelvis (ATFP), the sacrospinous ligament (SSL), and the coccygeus muscle (Fig. 83-1). The obturator foramen is

formed by the superior pubic ramus above, the pubic body and inferior ramus medially, and the anterior border of the ischial body below (Newell et al, 2005).

Muscular Supports of Pelvic Floor. The pelvic floor consists of all the soft tissues that essentially hold the pelvic viscera in place, including the muscular support, the fascial and ligamentous support, and the connective tissues. The pelvic floor is a three-dimensional structure that functions as a unit (Hurt, 2000). The pelvic diaphragm is composed of the levator ani muscles (which include the striated pubococcygeus and iliococcygeus muscles) and coccygeus muscles (Fig. 83-2). The coccygeus is also termed the *ischiococcygeus muscle* and is attached medially to the lateral margins of the coccyx and fifth sacral segment (Mundy, 2005) and laterally to the ischial spine. The iliococcygeus is attached to the ischial spine and the arcus tendineus levator ani laterally and the tip of the sacrum and coccyx posteriorly. The pubococcygeus is attached to the back of the pubis, and it courses lateral to the urethra (in males it is called the *pubourethralis*, and in females, because it forms a sling around the vagina, it is termed the *pubovaginalis*). In both men and women, fibers of the pubococcygeus attach to the perineal body (Mundy, 2005). The pubococcygeus compresses the visceral canals, which cross the pelvic floor. The puborectalis portion of the pubococcygeus helps to create the anorectal angle. Contraction of the puborectalis causes the rectoanal junction to move toward the pubic symphysis, which is critical in maintaining fecal continence (Rogers, 2003). **Although the muscles are referred to separately, like other structures of the pelvic floor, the boundaries are often difficult to delineate and they perform similar physiologic functions (Mundy, 2005).** The posterior levator ani group (iliococcygeus, pubococcygeus, and puborectalis muscles) fuses in the midline and attaches to the coccyx. The complex formed by this fusion is the levator plate, which serves as a supporting structure for the upper vagina and cervix. This not only serves to stabilize the upper vagina in a horizontal plane, but it also provides a protective mechanism preventing downward forces onto the perineal body (Wall and Menafee, 2002).

Beneath the pelvic diaphragm is the diamond-shaped urogenital diaphragm (Fig. 83-3). The boundaries are the pubic symphysis anteriorly, the tip of the coccyx posteriorly and laterally, and the ischiopubic rami on either side. It can be further divided anteriorly and posteriorly by imagining a line between the ischial tuberosities. This results in the urogenital triangle anteriorly and the anorectal triangle posteriorly. The deep transversus perinei muscle, also termed the *perineal membrane*, is contained by the urogenital triangle, in

Pelvic girdle, gluteal region and hip joint. In: Standring S, editor. Gray's anatomy: the anatomical basis of clinical practice. 39th ed. New York: Elsevier; 2005.)

Figure 83-3. Muscles of the female perineum. The cut edge on the right side is the cut edge of the superficial fascia that has been removed. The left side depicts the deep perineal muscles (as seen without the superficial perineal muscles and overlying fascia). (From Mundy A. True pelvis, pelvic floor and perineum. In: Standring S, editor. Gray's anatomy: the anatomical basis of clinical practice. 39th ed. New York: Elsevier; 2005.)

Figure 83-2. Muscles of the female pelvic diaphragm. (From Walters M, Karram M. Urogynecology and reconstructive pelvic surgery. 3rd ed. Philadelphia: Mosby; 2006.)

Figure 83-4. A and B, Perineal membrane. The two halves of this triangular sheet of fibromuscular connective tissue form a central tendon referred to as the *perineal body*. (Redrawn from DeLancey JO. Structural anatomy of the posterior pelvic compartment as it relates to rectocele. *Am J Obstet Gynecol* 1999;180:815–23.)

which the urethra and vagina traverse. In contrast to the perineal membrane in males, which is a sheetlike structure, the perineal membrane in females is a three-dimensional structure that has two regions, dorsal and ventral (Stein and DeLancey, 2008) (Fig. 83-4). The dorsal region is attached to the perineal body and the lateral wall of the vagina via the ischiopubic rami. The ventral region is part of a solid three-dimensional mass, which is contiguous with the paraurethral and paravaginal connective tissues. This portion contains the compressor urethrae and urethrovaginal sphincter muscles of the distal urethra (Stein and DeLancey, 2008).

The anorectal triangle contains the external anal sphincter, which attaches to the anococcygeal ligament and fuses to the superficial transversus muscle. External to the urogenital triangle are the external genital muscles, bulbospongiosus, ischiopubic rami, and superficial transversus perinei. The hymen is located just inside of the labia minora and is the fixed point of reference recommended by the International Continence Society Committee on Standardisation of Terminology, Sub-Committee on Pelvic Organ Prolapse and Pelvic Floor Dysfunction to grade prolapse (Bump et al, 1996). This is in contrast to the term *introitus*, which is ill defined.

The urogenital hiatus is the opening within the levator ani muscle through which the urethra and vagina pass. Because the rectum is attached directly to the muscles at this level, it is not within the urogenital hiatus. The hiatus is supported anteriorly by the pubic bones and levator ani muscles and posteriorly by the perineal body and external anal sphincter (Ashton-Miller and DeLancey, 2007). The urogenital hiatus elongates and descends with POP.

Endopelvic Fascia and Connective Tissue Supports. The endopelvic fascia is a network of fibromuscular tissue located between the peritoneum and the levator muscles. It surrounds and attaches the bladder, uterus, vagina, and rectum to the pelvic walls, thereby

Figure 83-5. Vaginal and visceral supportive structures as defined by DeLancey. The fibers of level I support are oriented vertically and suspend the uterus and upper vagina. Level II support is more horizontal in its orientation and attached to the midvagina. Distally, level III support fuses directly into the support structures. (From DeLancey JO. Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol* 1992;166:1717–28.)

stabilizing the pelvic viscera. The endopelvic fascia is one continuous unit; however, distinct areas are named separately. The parametrium (broad, cardinal, and uterosacral ligaments) attach the uterus and upper vagina to the pelvic sidewall. The paracolpium (the arcus tendineus levator ani and the ATFP) attach the vagina to the pelvic sidewalls. In his landmark article, DeLancey (1992) described the supports of the vagina and conceptually divided them into three parts according to the region of vaginal support (Fig. 83-5). The structures supporting the uterus and cephalad 2 to 3 cm of the vagina comprise level I support, and these fibers originate from the greater sciatic foramen, the sacroiliac region, and lateral sacrum. The fibers are primarily vertical in their orientation and are the longest fibers of the endopelvic fascia, thereby suspending the uterus and upper vagina, and comprise the cardinal-uterosacral ligament complex. Level II support is at the midvagina. These fibers are shorter than level I support but longer than those at level III. The orientation of the attaching fibers is lateral, and they are denser than the cardinal-uterosacral complex. The endopelvic fascia splits at this level to encompass the bladder and urethra such that the abdominal leaf is still named the *endopelvic fascia* and the vaginal leaf is termed the *pubocervical* (or *perivesical*) and *periurethral fascia*. Posteriorly, the endopelvic fascia, which attaches laterally to the superior fascia of the levator ani muscles, is the *rectovaginal fascia*. Level III support of the vagina starts at the introitus and extends 2 to 3 cm above the hymenal ring. In this most distal location there is no intervening paracolpium and the vagina is fused directly to the urethra and is embedded in the connective tissue of the perineal membrane (urogenital diaphragm.) Laterally, it blends into the medial margins of the levator ani muscles, and posteriorly it blends into the perineal body.

The endopelvic fascia is a composite of tissues of fibers embedded in a matrix. The variability of this tissue matrix may lead to its inherent weakness and inconsistency in reconstructive surgery. In fact, fresh strips of pubocervical fascia have been shown to shorten 15% to 20% of their length (Richardson and DeLancey, 2000). Thus, these tissues are supportive and contractile. Histologically, this tissue is unlike abdominal wall fascia or the fascial coverings of other muscles in that they lack the organization of the fascial coverings of the skeletal muscle.

Support by Compartment

Anterior Compartment Supports. Because the urethra is fused to the anterior vaginal wall for much of its length, the supporting structures of the urethra and distal anterior vagina are one and the same. The major components are the endopelvic fascia (periurethral and pubocervical or perivesical fascia), the ATRF, and the levator ani muscles (Ashton-Miller and DeLancey, 2007). At this level, the endopelvic fascia surrounds the vagina and attaches to the ATRF bilaterally. Each ATRF stretches from the inner aspect of the ischial spine across the belly of the obturator internus muscle and terminates at the lower margin of the posterior pubic bone. This structure appears as a band closer to the pubic bone and, as it courses toward the ischial spine, fans out into a broad aponeurotic structure. Laterally it merges with the levator ani muscles at the confluence of the iliococcygeus and obturator internus muscles.

Apical (Middle) Compartment Supports. This support is provided by the cardinal-uterosacral ligament complex, level I supports as described by DeLancey (1992). They originate from fibers of the pelvic sidewall and extend to the area around the greater sciatic foramen, and to the second, third, and fourth sacral segments. From here, they fan out as they attach to the cervix and the upper vagina. The medial edge of this complex is the area of the uterosacral ligaments. The uterosacral ligaments are visible and palpable with traction of the cervix or the cuff of the vagina after hysterectomy. The fibers encircle the cervix and in aggregate are called the pericervical ring.

Posterior Compartment Supports. The rectovaginal fascia is also sometimes referred to as the *Denonvilliers fascia* in the female (Richardson and DeLancey, 2000). It has denser strands of elastin and less smooth muscle compared with the pubocervical fascia. It is stabilized in the upper vagina by the cardinal-uterosacral complex, as it is contiguous with this structure. The uterosacral ligament inserts into the rectovaginal fascia just below the attachment to the posterior cervix. Because the rectovaginal fascia is connected to the sacrum and the perineal body, it provides continuous posterior support.

The perineal body is a condensation of fibromuscular tissue and collagen, which is located in the midline between the vagina and the anus. It serves as a point of fixation for the rectovaginal fascia, the levator ani muscles, the transversus perinei muscles, and the external anal sphincter (Rosenblum et al, 2005).

Pathophysiology of Pelvic Organ Prolapse: Surgical Correlation

The levator ani muscles are composed of both type I and type II muscle fibers. Type I muscle fibers are slow-twitch fibers and provide sustained tonicity of the pelvic floor. This function serves a crucial role in providing dynamic pelvic floor support, thus taking the mechanical stress off of the endopelvic connective tissue attachments. Type II fibers are fast-twitch fibers that are mainly responsible for the reflex contractions of the pelvic floor associated with sudden increases in intra-abdominal pressure. Thus, the levator ani muscle complex fulfills multiple functions. First, the tonic contraction of the pubococcygeus muscle narrows the genital hiatus. Second, contraction of the pelvic floor leads to the elongation and elevation of the pelvic organs facilitating urinary and fecal continence. In addition, posterior levator ani tonicity elevates the upper vagina and stabilizes it into a horizontal plane near the hollow of the sacrum (Fig. 83-6) (Wall and Menafee, 2002). Direct muscular damage, neuromuscular dysfunction, and inherent tissue defects may predispose to a dysfunction of the levator ani musculature. As a result, the burden of support shifts mostly to the endopelvic connective tissues. As these structures weaken, various “breaks” occur that lead to vaginal support defects.

It is most useful to define defects by compartment while keeping in mind that many patients have multicompartments defects. In addition, some patients will have several defects within the same compartment.

Figure 83-6. Function of the levator ani. The tonic contraction of the pubococcygeus muscle narrows the genital hiatus and leads to elongation and elevation of the pelvic organs, facilitating continence (A, at rest; B, contracted). The posterior levator ani elevates the upper vagina and stabilize it on the levator plate, which provides a supportive role to the perineal body.

SITE-SPECIFIC DEFECTS BY COMPARTMENT (IDENTIFICATION)

See Table 83-1.

Anterior Compartment

Within the anterior compartment, two types of defects can lead to cystoceles. The **central cystocele** results from attenuation or separation of the pubocervical fascia, resulting in a protrusion of anterior compartment structures through this defect. This protrusion results in the classic appearance of a loss of the rugae or vaginal folds of the anterior vaginal wall. Detachment of the pubocervical fascia and the pubourethral ligaments to the ATRF results in a **lateral cystocele** and can also involve the urethra. This usually results in a preservation of the rugal folds of the vaginal wall, and a “rotational” prolapse of the anterior wall (Fig. 83-7). **Urethroceles**, which are distal anterior compartment defects, usually result in urethral hypermobility (Weber and Walters, 1997).

TABLE 83-1 Compartmental Anatomy: Pelvic Organ Prolapse Quantification System (POP-Q) Sites and Organ Involvement

COMPARTMENT	POP-Q SITE	PROLAPSED ORGAN	VAGINAL WALL SITE
Anterior compartment	Aa	Urethrocele	Distal anterior vaginal wall
	Ab	Cystocele	Proximal anterior vaginal wall
Middle compartment	C	Cervix	Cervix
	D	Vaginal cuff	Vaginal cuff
		Enterocele	Uterosacral scar
Posterior compartment	Ap	Enterocele	Proximal posterior vaginal wall
	Bp	Rectocele	Distal posterior vaginal wall
		Perineal body defects	Perineal body

**Figure 83-7.** Cystoceles. Note the appearance of central and lateral defects. (From Baggish M, Karram M. *Atlas of pelvic anatomy and gynecologic surgery*. 3rd ed. Philadelphia: Saunders; 2010.)

Apical Compartment

Apical compartment defects involve a disruption in the uterosacral-cardinal ligament complex. This defect may lead to prolapse of the uterus, the vaginal cuff after hysterectomy, and the peritoneum cul-de-sac with or without bowel (enterocele). Enterocèles are most commonly associated with apical or high posterior compartment defects; however, enterocèles may rarely occur anteriorly. Enterocèles can occur with or without vaginal vault prolapse. Complete vaginal vault prolapse contains an enterocele in 75% of patients. Waters described four types of enterocèles by cause: congenital, pulsion, traction, and iatrogenic (Waters, 1956). Congenital enterocèles occur either from the failure of the peritoneum to fuse with the perineal body or from reopening of previously

fused structures. Pulsion defects occur with increased intra-abdominal pressures, and traction enterocèles occur by a pulling of the vaginal epithelium from other prolapsing organs. Iatrogenic enterocèles are created when a surgical procedure is performed that alters the normal vaginal axis or when the pubocervical fascia and the rectovaginal septum are not reapproximated after hysterectomy (Wiskind et al, 1992).

Uterine prolapse occurs with loss of support of the cardinal and uterosacral ligaments. The broad ligaments also provide uterine support and are located above insertion of the cardinal uterosacral ligaments. They are located within the leaves of the anterior and posterior peritoneum. Within this fused structure are the fallopian tubes and the round and ovarian ligaments along with their blood supply (Rosenblum et al, 2005). It is difficult to differentiate other prolapsing organs with loss of apical support high in the vagina. Accordingly, careful dissection is often needed to identify other prolapsing organs with uterine prolapse. This reinforces the concept that the endopelvic fascia is best considered as a contiguous unit that can fail together. Consequently, the bladder, small bowel, and rectum are often found prolapsing with the uterus.

Vaginal vault prolapse can occur after hysterectomy if support of the vault is not reconstituted by suspending it to the cardinal uterosacral ligament complex. Incidence of vaginal vault prolapse after hysterectomy has been reported to be as high as 18.2%, and it can contribute to prolapse in other compartments (Richter, 1982). Because of the redundancy of the support by the endopelvic fascia, failure to reattach the suspensory component does not lead to immediate vaginal eversion after hysterectomy (DeLancey, 1992). Complex vaginal eversion is vaginal eversion associated with cystocele, rectocele, or both (DeLancey, 1992). Complex vaginal eversion has been reported as high as 67% of vault prolapse (Morley and DeLancey, 1988). In this group of patients, 7% had apical prolapse and cystocele, 30% had apical prolapse with rectocele, and 30% had apical prolapse with both cystocele and rectocele.

Posterior Compartment

The posterior vaginal compartment is composed of the peritoneum of the cul-de-sac, the rectum, and the perineum. Defects in the rectovaginal fascia in the form of either attenuated fascia or site-specific tears will result in herniation of the rectum and sometimes the small bowel into the vagina. Rectocèles may be divided into low, midvaginal, or high depending on the location of loss of support, and they may occur with a combination of defects. Richardson was the first to describe site-specific defects of the rectovaginal fascia, in 1993 (Richardson, 1993) (Fig. 83-8). Defects in the cardinal-uterosacral ligament complex can result in high rectocèles and can involve enterocèles. Enterocèles are estimated to be present in 0.1% to 16% of women undergoing surgery for POP (Chou et al, 2000). Loss of support in the midvagina from the lateral attachments to the arcus tendineus fascia rectovaginalis will result in a bulging in the midportion of the posterior compartment. The

Figure 83-8. Locations where breaks in the rectovaginal septum have been observed in patients with posterior defects.

Figure 83-9. Large rectocele with perineal body defect. (From Nichols DH. Rectocele and perineal defect. In: Nichols DH, editor. *Gynecologic and obstetric surgery*. St. Louis: Mosby; 1993. p. 363–85.)

perineal body is suspended from the sacrum by the contiguous support of the uterosacral ligaments and rectovaginal septum. Any break in this support system will lead to a hypermobile perineal body, which descends with increases in intra-abdominal pressures (Richardson, 1993). Separation of the perineal body at the level of the rectovaginal fascia results in perineal descent or a low rectocele. The rectocele will be visible just inside of the hymen posteriorly (Fig. 83-9). If perineal body detachment is left untreated at the time of rectocele repair, a perineal rectocele can occur in which the rectum bulges into the perineal body, termed a *perineal rectocele* (Richardson, 1995).

PREPARING THE PATIENT FOR PROLAPSE SURGERY

Because POP is, for the most part, a QoL issue, consideration must be given to the grade of prolapse, the patient's symptoms, and the degree to which the patient's QoL is impaired (Novara and Artibani, 2005). In selecting surgical procedure(s), one must individualize management based on the unique clinical presentation of each patient, taking into account physiologic age, comorbidities, previ-

KEY POINTS: PELVIC FLOOR ANATOMY

- POP occurs as compartmental defects of vaginal support. The three compartments are anterior, apical (middle), and posterior.
- Vaginal support or attachment is provided by the endopelvic connective tissues. The cardinal and uterosacral ligaments provide level I support of the uterus and upper vagina. The endopelvic and pubocervical fasciae provide level II support of the midvagina as it attaches to the ATFP. Level III support of the distal vagina attaches to the levator ani muscles and the perineal body.
- The pelvic diaphragm consists of the coccygeus, iliococcygeus, and pubococcygeus muscles. These muscles provide an important function in maintaining continence and pelvic floor support.
- Pelvic floor defects originate from generalized weakening of endopelvic connective tissue and from breaks in sites of vaginal attachment as the pelvic floor muscles and endopelvic connective tissue weaken.

ous surgeries, and level of physical and sexual activity, as well as overall bother from POP symptoms (Flynn and Webster, 2002). Once the decision has been made to proceed with surgery, it is imperative to recall that **the best chance at restoring normal support and function is most likely associated with the first surgery** (Rogers, 2003). After the first procedure, the normal anatomic planes will no longer be present, which may add to the difficulty and complexity of subsequent surgeries. Recurrence rates increase with each attempt to surgically correct the defect(s) (Birch, 2005; Maher and Baessler, 2006a, 2006b). In addition, the pelvic floor surgeon must understand the anatomic alterations that result from each technique and how that surgery will affect the continuity and function of the endopelvic fascia and its related viscera (Rogers, 2003). A preoperative discussion is warranted to inform the patient of the anticipated risks and benefits of each surgical option so that she can choose the type of operation (if any) is best for her. Some may feel that their level of bother may not warrant the risks of prolapse surgery, and that is a reasonable informed decision.

Prolapse repairs can be defined as **restorative, compensatory, and obliterative** (Van Rooyen and Cundiff, 2008). In patients whose comorbidities preclude prolonged surgery, **obliterative procedures** may offer symptom relief with minimal morbidity. These procedures are contraindicated in patients who wish to remain sexually active; however, for the right candidate these procedures can greatly reduce symptoms with favorable risk. For those patients who have discrete defects in the fibromuscular layer of the endopelvic fascia, **restorative repairs** are an appropriate option. These repairs correct the defined defects in the native tissues by using endogenous support structures. For patients whose native tissues are particularly weak or for those who have had failed surgeries, **compensatory procedures** have been used. These procedures involve placing a graft to reinforce the repair. Grafts are made of synthetic materials and biologic and autologous tissues.

Pelvic floor reconstruction may be performed through a vaginal, open abdominal, laparoscopic, or robotic approach or any combination of these techniques. Because POP is often mixed, surgery commonly involves a combination of repairs addressing any affected compartments. In addition, an anti-incontinence procedure may be performed at the same time. **When comparing vaginal and abdominal approaches to prolapse surgery, a general consensus is that there is a benefit with the vaginal approach, which is usually associated with decreased complications and recovery time** (Weber and Richter, 2005). The operative time is typically less with the vaginal approach, as are the hospital stay and recovery time (Morley and DeLancey, 1988; Shull, 1999). These comparisons must be viewed in the context of emerging laparoscopic and robotic

approaches to POP repair. Recovery times appear improved with these techniques, making these repairs more feasible. **When evaluating outcomes, there is evidence that the abdominal approach is more durable compared with vaginal techniques (Benson et al, 1996).** It is important that all of these factors be considered when selecting the proper technique for each patient.

Preoperative Counseling of the Patient for Vaginal Pelvic Organ Prolapse Surgery

The concept of measuring success of prolapse surgery is in evolution. It is clear that success of prolapse surgery is not just objective resolution of the anatomic defects. The absence of patient symptoms, whether resolution of vaginal bulging or minimization of de novo postoperative symptoms, has the strongest correlation with the patient's assessment of overall improvement and treatment success (Barber et al, 2009b). Thus, **the concept (and definition) of success must include patient satisfaction and symptom improvement, in addition to objective measures.** This process begins before the operation, because patients' expectations and readiness to undergo surgery for POP has been shown to affect their satisfaction and how they perceive their improvement (Kenton et al, 2007). Elkadry and colleagues found that patient satisfaction after surgery for POP correlated highly with achievement of self-described goals (Elkadry et al, 2003). Thus, it is very useful to ask patients, "What are you expecting after surgery? What changes do you desire?" Furthermore, patients perceived the experience of routine postoperative events such as pain, hospital discharge with a catheter, constipation, urge incontinence, and minor effects of anesthesia as surgical complications. These perceived complications were also associated with dissatisfaction, which existed despite high cure rates. Thus a feeling of being unprepared for surgery was highly associated with a negative perception of outcome. **Negative patient perception equates largely to postoperative dissatisfaction even in the presence of high objective cure rates. It is vitally important to recognize that the absence of symptoms influences patient satisfaction to a greater degree than the elimination of anatomic prolapse.** Kenton and colleagues evaluated patients with standardized counseling, giving a three-page handout on what to expect after surgery (Kenton et al, 2007). Women who perceived they were fully prepared for surgery were more likely to be improved on the Patient Global Impression of Improvement (PGI-I) scale (Yalcin et al, 2003) and had lower postoperative scores on the Pelvic Organ Prolapse Distress Inventory (POPDI) (Barber et al, 2001) and Urinary Distress Inventory (UDI) (Shumaker et al, 1994). Also, Kenton and colleagues found that objective measures of cure did not differ by preparedness. In conclusion, **the preoperative surgeon-patient interaction is vitally important and may facilitate improved postoperative patient satisfaction.** Therefore it is recommended to have a thorough discussion while obtaining informed consent about the surgery, alternatives to surgery, the purpose of the planned surgery (what it can and cannot accomplish), the benefits of surgery (what symptoms can be improved), and the risks and complications. In addition, it is useful to review what to expect while the patient is in the hospital, what to expect at home, and strategies for coping with a catheter both in the hospital and at home if needed (Kenton et al, 2007).

BIOLOGIC AND SYNTHETIC MATERIALS IN PROLAPSE SURGERY

Pelvic surgeons have long struggled with recurrences of prolapse after surgical correction. It is estimated that 29% of women require reoperation for incontinence and prolapse (Olsen et al, 1997). The risk factors for failure of prolapse surgery include increasing age, vaginal parity, smoking, deficient tissue quality, conditions that impair wound healing (diabetes mellitus and steroid use), and conditions that stress the repair (chronic constipation, chronic obstructive pulmonary disease, and obesity.) When examining

KEY POINTS: PREOPERATIVE COUNSELING FOR PELVIC ORGAN PROLAPSE SURGERY

- The **absence** of recurrent prolapse **symptoms** influences patient satisfaction more than the elimination of anatomic prolapse.
- It is vitally important to understand the patients' goals and expectations of surgery and to carefully review the risks and benefits of each surgical approach.
- Postoperative "events" such as catheterization or urinary tract infection (UTI) are significant to the patient and negatively influence perception of outcomes.
- The discussion preceding the preoperative informed consent is a valuable time to review the patient's goals and expectations as well as to discuss the risks and benefits of each surgical option.
- It is important for the patient to be educated on what to expect throughout the perioperative course; patients may perceive perioperative events as "complications," which has a negative effect on the overall perception of the procedure.

the issue of failed prolapse surgery, there are limitations. The definition of failure is not standardized, and many studies are short term, lacking controls. However, in spite of the limitations, **it is clear that failure of prolapse surgery is not uncommon.** Some patients with POP have specific deficiencies in their tissues, which may predispose them to failure with traditional restorative procedures. Abnormal type I-to-type III collagen ratios have been identified, leading to a less organized collagen matrix (Falconer et al, 1998). Normal collagen protects fibroblasts from apoptosis, whereas abnormal fibroblasts are not protective (He et al, 2002). Decreased numbers and impaired function of fibroblasts have also been cited (Poncet et al, 2005). Overexpression of matrix metalloproteinases, which break down extracellular matrix proteins, have been demonstrated in women with prolapse (Jackson et al, 1996). These factors imply that these affected tissues may be less likely to respond to the dynamic forces placed on the female pelvic floor (Chen et al, 2004). As a result of these potential tissue disorders and inherent tissue weakness, graft interposition has been used in an effort to improve outcomes of transvaginal prolapse repairs. Although there is level 1 evidence supporting the use of synthetic graft materials for abdominal sacral colpopexy procedures (Davila et al, 2005), there is little evidence regarding the most appropriate use of transvaginal mesh (TVM) in prolapse repairs.

Classification of Graft Materials

The ideal prosthetic implant would be biocompatible, chemically inert, noncarcinogenic, mechanically strong, and sterile; would cause minimal allergic or inflammatory reaction; and would avoid shrinkage and mechanical stress (Birch, 2005). In addition, the ideal implant should be readily available and affordable. Grafts may be categorized as either synthetic or biologic, and both graft types are used in pelvic floor reconstruction. Synthetic graft materials are usually classified as absorbable or nonabsorbable (permanent). Permanent graft materials are usually classified by pore size (macroporous, microporous, submicroporous, and combined) and material structure (monofilament or multifilament). Biologic grafts are classified by source: autologous or heterologous, with the latter further categorized as allografts or xenografts (Fig. 83-10).

Basic Science: Graft-Host Interaction

Graft incorporation of the tissues involves a foreign body response. Although many materials used for synthetic grafts are reported to be chemically and physically inert and nonimmunogenic (Davila et al, 2005; Deprest et al, 2006), none are biologically inert.

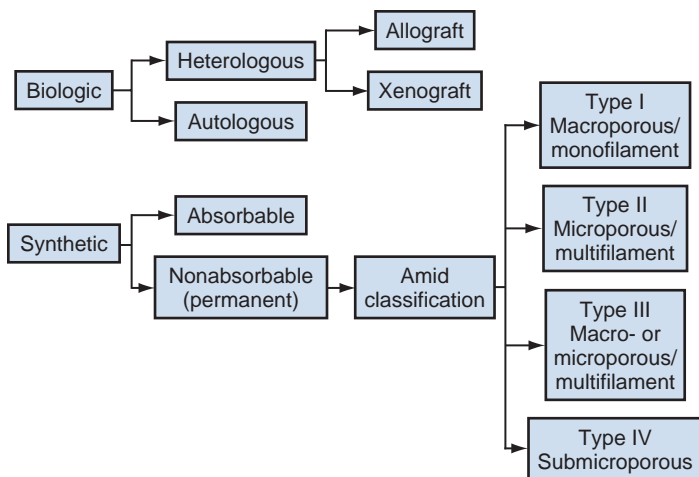

Figure 83-10. Classification of graft materials. (From Togami J, Krlin R, Winters J. Graft materials in prolapse surgery. *AUA Update Series* 2008;27:294–303.)

Regardless of the material type, wound healing with a graft follows a stepwise cascade. Initially a biofilm is produced in response to tissue injury. Low-molecular-weight protein adsorption occurs quickly at the interface and does not require a cellular response. Complex proteins such as fibrinogen, immunoglobulins, and extracellular matrix proteins follow. If bacteria are incorporated into the biofilm at this point, it can affect later wound healing (Deprest et al, 2006). These complex proteins undergo a conformational change to become more immunogenic, which leads to an inflammatory cascade by activating complement, binding antibodies, leukocytes, blood clotting, and fibrinolysis (Tang and Eaton, 1995). At this point the acute inflammatory response becomes chronic, and granulation tissue forms. This involves fibroblasts, macrophages, and giant cells and, later, neovascularization and fibrosis. At this point the implant is mechanically stable. The amount of foreign body reaction is proportional to the surface area of the material exposed to the host. **The degree of response and amount of tissue ingrowth is determined by the nature of the material, its structure, and the amount implanted for biologic grafts (Deprest et al, 2006).** Ideally, host-tissue integration into the graft takes place, leading to long-term graft function after this biologic transformation. This illustrates an important concept in that **the graft, biologic or synthetic, acts as a scaffold to provide a substrate to facilitate tissue ingrowth, rather than functioning as a permanent mechanical support (Birch, 2005).**

Once a graft has been implanted into the human host, one of four processes may occur: rejection, in which there is severe and chronic inflammatory reaction around the implant; degeneration (the result is necrosis from in situ exothermic polymerization by the host); encapsulation (minimal foreign body response in which there is fibrosis around the graft); or incorporation into the human host tissue (response in which there are inflammatory cells and giant cells leading to ingrowth of host tissues into the graft) (Williams, 1973). For long-term graft survival, it appears that **incorporation by the host through a process known as graft remodeling is necessary (Fig. 83-11).**

Pore size affects host fibroblast infiltration, flexibility, and mechanical integration of the graft (Klinge et al, 2002). Large pore size has been shown to facilitate this process by enhancing host tissue infiltration and reducing the amount of inflammatory reaction with increased fibroblast infiltration. The large pores become integrated in a loose network of perifilament granulomas filled with fat, which maintains elasticity. After ingrowth of host tissue, a process of transformation occurs to complete the process of remodeling. Solid products or products with small pores (<50 μm) induce a foreign body reaction, which fills the entire pore.

Figure 83-11. Host tissue ingrowth (process of graft remodeling) into polypropylene mesh. (From Woodruff A, Cole E, Scarpero H, et al. A histologic analysis of sling graft materials: a comparative study. *Urology* 2008;72:85–9.)

This promotes bridging of the filaments to one another, thereby predisposing to encapsulation (Beets et al, 1996).

Kaupp and colleagues described four histologic stages of the host to biologic graft implantation (Kaupp et al, 1979). Stage 1 occurs over the first 7 days. This is marked by intense inflammation around the graft, which induces capillary proliferation, formation of granular tissue, and presence of giant cells. Stage 2 encompasses the next 7 days. Granular tissues are still present, and foamy histiocytes appear. Giant cells may increase or decrease at this point. Stage 3 spans days 21 to 28, when the acute inflammation dissipates with decreased capillaries. Foamy histiocytes and giant cells increase in number. Stage 4 happens after 28 days. Giant cells are present on the surface of the implant along with dense fibrotic tissue. This initiates the process of the host-graft interaction.

Once the entire graft is infiltrated with host tissue, the transformation process is complete. If this remodeling process characterized by ingrowth and transformation occurs before the graft substrate dissolves, long-term viability of the implant may be ensured. Although synthetic mesh material is a permanent substrate, the principles of tissue incorporation are necessary to prevent infection, extrusion, or erosion. Extrusion is thought to be secondary to exposed graft, which is attributable to localized infection, inadequate closure of the wound, or poor tissue quality (decreased vascularity or thickness) (Birch, 2005).

Clinical Application of Graft Materials

Biologic Grafts

Owing to concerns regarding potential complications associated with synthetic grafts, some authors have turned to biologic grafts to circumvent these complications (Togami et al, 2008). Biologic grafts are categorized as **autologous** (patient serves as the donor), **allografts** (same species, different individual [cadaveric]), and **xenogeneic** (obtained from other species, typically pig). The advantages of biologic grafts include in vivo tissue remodeling, histologic similarity, and decreased propensity to elicit local complications (Silva et al, 2005).

The donor sites for autologous grafts include rectus fascia, fascia lata, and vaginal epithelium, with the most common being rectus fascia and fascia lata. **Autologous grafts are ideal in that they are well incorporated, pose no threat of disease transmission, and have minimal risk of encapsulation or rejection.** The major drawback is the harvesting process, with increased morbidity, time, and potential for complications at the donor site. These factors are eliminated by using allografts and xenografts (Jarvis and Fowlie, 1985). **Allografts** are obtained from cadaveric donors and include dura mater, fascia lata, and dermis. Cadaveric fascia lata and dermis are used most commonly. A major concern when using biologic materials is the potential for disease transmission. Choe and Bell

demonstrated intact DNA in freeze-dried irradiated cadaveric fascia lata and freeze-dried cadaveric dermal allograft (Choe and Bell, 2001). Fitzgerald and colleagues also examined irradiated freeze-dried or solvent dehydrated cadaveric fascia lata and found that it retained the donor human leukocyte antigen (HLA) class I and II antigens (Fitzgerald et al, 2000). Although extensive steps are taken to prevent infection exposure, risk of prion and human immunodeficiency virus (HIV) transmission is estimated to be 1 in 1.7 million (Buck et al, 1989). To date, there have not been any reports of disease transmission from grafts used for POP.

The harvesting techniques of nonautologous biologic graft materials are standardized. In their review, Chen and colleagues described the process of allograft acquisition (Chen et al, 2007). Before allografts are harvested, the donor undergoes serologic testing for hepatitis B and C, HIV, and human T-lymphotropic virus 1. Aseptic technique is used during harvest, and cultures are obtained at the time. The source animals for xenografts are specifically raised for medical purposes, with production being strictly controlled by U.S. Food and Drug Administration (FDA) guidelines (Deprest et al, 2006). Materials available are derived from porcine subintestinal mucosa, porcine dermis, bovine dermis, and bovine pericardium, although the most commonly used are from porcine sources. These function as acellular collagen-based scaffolds, to serve as a platform for host infiltration.

Allografts and xenografts must undergo tissue processing before implantation, and unlike with harvesting, there is a variance in the processing techniques of these materials. This variance may affect the biologic and biomechanical properties of the grafts. There is no consensus as to which method should be used to optimize tissue properties. In some cases, processing is carried out to affect the long-term effects of the tissue to decrease graft breakdown and increase host tissue ingrowth. Sterilization is achieved by freeze-drying, solvent dehydration, and/or gamma irradiation. Lemer and colleagues demonstrated that freeze-dried cadaveric fascia demonstrated the least desirable characteristics when compared with autologous rectus fascia, cadaveric dermis, and solvent dehydrated cadaveric fascia lata (Lemer et al, 1999). The freeze-dried cadaveric fascia demonstrated a reduced maximum load to failure and stiffness. In addition, there was greater variability in the tissue's strength and stiffness throughout its entire length.

Cross-linking is another processing technique that can affect graft performance. Cross-linking is done to delay reabsorption by collagenases (Badyalak et al, 2002). Several methods are used, including aldehyde cross-linking and hexamethylene diisocyanate (HMDI). Aldehydes are cytotoxic in high concentrations and may increase concentrations of gelatinases, which may actually increase the rate of degradation (Jorge-Herrero et al, 2001). In addition, aldehydes may cause calcification of the grafts, adversely affecting their function. Studies carried out in rats have shown no graft mineralization with HMDI cross-linked dermal implantation at 2 years in contrast to aldehydes (Oliver, 1987). Although cross-linking may be done to stabilize the implant and delay degradation, there are concerns that this process may impede host tissue infiltration and potentially lead to encapsulation. Although these concerns have never been evaluated in a definitive trial, it seems logical that these variances in processing may ultimately lead to variance in biologic graft performance.

Local complications such as encapsulation may occur after the use of porcine dermis grafts (Cole et al, 2003). Graft fenestrations have been reported to enhance ingrowth and angiogenesis (Taylor et al, 2008). They may also decrease seroma formation and local complications. Porcine small intestinal submucosa (SIS) (Surgisis, Cook Medical, Bloomington, IN) is a non-cross-linked graft processed so that the complex extracellular matrix and natural growth factors are left intact. There is histologic evidence that by 1 month the strength and histology of the graft are identical to those of native material, and at 2 years the strength of the graft exceeds the strength of native tissue—although this has not been demonstrated definitively (Konstantinovic et al, 2005).

The lack of in vivo data limits the study of many biologic and synthetic grafts. Naturally, it would be of benefit to demonstrate

how the biomechanical properties of these materials are altered or remodeled by the host. Several animal models have been used to study grafts and meshes. In the rabbit model, a free or pedicle flap of autologous rectus fascia decreased 37% in length, 63% in width, and 53% in tensile strength after implantation for 12 weeks. Neovascularization, minimal inflammation, and fibrosis were noted only along the permanent suture used to secure the graft (Fokaefs et al, 1997). In a rabbit model, freeze-dried, irradiated cadaveric fascia lata had a 90% decrease in tensile strength 12 weeks after implantation (Walter et al, 2003). There was variability in tensile strength from lot to lot and from grafts taken from different areas in the same lot. In an extensive rabbit study examining six different graft materials, tensile strength and stiffness of human cadaveric fascia and porcine xenografts decreased by 60% to 89%. Polypropylene mesh and anterior rectus fascia had no change in tensile strength from baseline (Dora et al, 2004). When comparing Gynecare TVT (Ethicon, Somerville, NJ) polypropylene sling with cadaveric fascia lata sling in the rat model, there was an advantage for the polypropylene sling in the break load and maximum average load compared with cadaveric fascia lata (Spiess et al, 2004). **There is a wide variation in the types of grafts available and the tissue processing they undergo. It is unclear how this affects the performance of the grafts because there are few data comparing them.** Before implantation, dermal allografts, solvent dehydrated fascia lata, and synthetic mesh have equal or higher tensile strength compared with autologous fascia. In some studies, freeze-dried grafts have a decreased tensile strength compared with similar grafts that have been solvent dehydrated. After implantation, autologous fascia and synthetic mesh seem to retain more of their tensile strength compared with allografts or xenografts (Chen et al, 2007).

Synthetic Grafts

Synthetic mesh is available as permanent or absorbable material. Absorbable mesh has several desirable characteristics. It promotes postoperative fibroblast activity, has less infectious disease risk, is not rejected, and has not been reported to be harmful to the viscera. One disadvantage is that the resultant scar tissue may not be as strong as the native tissue it is reinforcing (Klinge et al, 2001). **Classification of the synthetic meshes occurs by type of mesh (absorbable or nonabsorbable), pore size (macroporous or microporous), and filament type (monofilament or multifilament).** Two types of absorbable meshes are available: polyglycolic acid (Dexon, Davis and Geck, American Cyanamid, Danbury, CT) and polyglactin 910 (Vicryl, Ethicon). They differ in the duration in the tissues. Polyglactin 910 starts to hydrolyze by 21 days and loses its mechanical support by 30 days. Polyglycolic acid takes 90 days for absorption.

The most important characteristic of a synthetic mesh is its pore size. Meshes are divided into macroporous (greater than 75 microns) or microporous (less than 10 microns.) Pore size is important from the standpoint of infection because it determines whether cellular elements such as macrophages and granulocytes will be able to enter the mesh construct. In addition, it is important for tissue ingrowth with fibroblasts, blood vessels, and collagen fibrils (Amid, 1997; Deprest et al, 2006; Dwyer, 2006) (Fig. 83-12). Most bacteria are smaller than 1 μm , and granulocytes and macrophages are greater than 10 μm in diameter, but **75 μm is the key number, which allows the tissue ingrowth.** Pore size also determines the flexural rigidity. The larger the pore size, the more flexible the mesh (Dietz et al, 2003). This property may affect local tissue trauma and erosive risk (Birch, 2005).

Synthetic mesh can be monofilament or multifilament. Multifilament synthetics may have pore sizes that allow them to be classified as macroporous; however, between the fibers the size is less than 10 microns because of the way the fibers are either woven or knitted. The spaces are small enough to allow bacteria into confines less than 10 microns, which carries a greater theoretic risk than a monofilament mesh. The construct of the mesh affects pore size, and the interstitial distance is measured between the synthetic

Figure 83-12. Synthetic graft pore and interstices: Note the multifilamentous nature of Mersilene, which may promote bacterial adherence. (From Togami J, Krlin R, Winters J. Graft materials in prolapse surgery. *AUA Update Series* 2008;27:294–303.)

fibers. Woven mesh has small pore size and interstices, whereas knitted materials are able to assume a macroporous configuration and are flexible with high tissue conformity.

Although there is no classification system specifically used for mesh in pelvic floor reconstruction, the Amid classification, which was originally used to describe mesh used in the treatment of abdominal wall hernias, is currently our standard (Amid, 1997). This classification emphasizes the importance of pore size and filament type (see Fig. 83-10).

Type I promotes host defenses and tissue infiltration. Type II and type III meshes result in a greater foreign body response and are associated with greater rates of erosion (Julian, 1996; Debodinance et al, 1999). The most desirable synthetic materials for pelvic floor reconstruction are lightweight, monofilament, macroporous mesh, most commonly polypropylene mesh. These meshes (of which many types are now commercially available) appear to be best tolerated in prolapse surgeries. In animal models, there is evidence that stiffness (degree of stretch when a force is applied to them) may be associated with the structural integrity of the vagina after implantation of lightweight polypropylene mesh. Implantation with stiffer polypropylene meshes resulted in increased collagenase activity and decreased collagen and elastin content. These changes resulted in deterioration of the mechanical properties of the vagina in an animal model (Feola et al, 2013; Liang et al, 2013). The clinical significance of these findings is unknown; however, further comparative studies on the various types of polypropylene meshes are warranted.

SURGICAL MANAGEMENT OF PELVIC ORGAN PROLAPSE

See Table 83-2.

Anterior Compartment

Anterior Colporrhaphy

Kelly first described his method of cystocele repair as a treatment for urinary incontinence (Kelly, 1913). He emphasized the importance of repairing the pubocervical fascia with plication sutures to repair the central defect in the anterior vaginal wall. This procedure eventually became known as the *anterior colporrhaphy* or *native tissue cystocele repair* and is now used for the treatment of anterior prolapse. Use for the treatment of incontinence diminished after the American Urological Association (AUA) Female Stress Urinary Incontinence Clinical Guidelines Panel meta-analysis found a failure of nearly 40% (Leach et al, 1997).

Anterior compartment defects are commonly combined central and lateral defects. Thus, an anterior colporrhaphy, which corrects only central compartment defects, usually must be combined with a paravaginal repair or lateral anchoring for the treatment of anterior wall prolapse. Isolated central defects are rare, and in these instances colporrhaphy alone may suffice. The early series on anterior colporrhaphy for the treatment of anterior vaginal wall prolapse reported objective success rates of 80% to 100%

POP-Q, Pelvic Organ Prolapse Quantification System.

(Macer, 1978; Stanton et al, 1982; Walter et al, 1982; Porges and Smilen, 1994). In 2001, Weber and colleagues in a randomized trial of three surgical techniques reported a 70% failure rate of native tissue anterior repairs (Weber et al, 2001). Recent reanalysis of this data set using a more contemporary and agreed-on definition of failure (prolapse beyond the hymen) reported a significantly better anatomic outcome, with only 10% of patients experiencing prolapse beyond the hymen and only 5% of patients reporting symptomatic improvement (Chmielewski et al, 2011). The extreme differences in failure rates for anterior colporrhaphy seen in the literature can be primarily explained by the variability in definition of failure and the fact that in early series these procedures were performed in patients with multiple defects.

Technique (Fig. 83-13). The patient is placed in the dorsal lithotomy position with all pressure points padded and the hip and knee joints flexed approximately 90 degrees. Preparation of the surgical area and cleansing of the vaginal and perivaginal tissue are recommended. Fixed or handheld retraction can be helpful and in general depends on patient body habitus as well as availability of surgical staff for assistance. An indwelling urethral catheter is placed and the bladder is drained either continuously or intermittently throughout the procedure. Hydrodissection may be used to facilitate the dissection. A midline incision is made in the anterior vaginal wall, extending from the vaginal apex to the bladder neck. The incision should not extend to the urethra when a simultaneous mid-urethral sling is anticipated. Optimally, the sling should be placed through a separate, mid-urethral incision. However, when performing a pubo-vaginal sling, it is desirable to create one incision that extends from the vaginal apex to the mid-urethra to facilitate more precise sling positioning over the bladder neck. The vaginal wall is dissected off the pubocervical fascia starting in the midline and advancing laterally to the ATPF. This dissection should allow sufficient visualization to delineate both central and lateral defects. Allis clamps or a self-retaining ring retractor may be used to provide optimal exposure.

Figure 83-13. Anterior colporrhaphy. The anterior submucosal layer is imbricated with 2-0 delayed absorbable continuous or interrupted suture. (From Nicholas DH. Cystocele. In Nichols DH, editor. Gynecologic and obstetric surgery. St. Louis: Mosby; 1993. p. 334–62.)

The bladder is then reduced with a finger or instrument to facilitate lateral exposure and reapproximation of the lateral pubocervical tissues in the midline. Interrupted 2-0 or 3-0 delayed absorbable plication sutures are placed from the bladder neck to the apex in a sequential fashion. The plication sutures are then tied as the assistant reduces the prolapsed tissue. Care must be taken to avoid excessively deep suture placement that may penetrate the bladder or ureteral lumens or kink the distal ureters or intramural tunnels. Augmented repairs use allograft or mesh to reinforce the plication sutures (see the later discussion of augmented repairs). Excess anterior vaginal wall may be judiciously trimmed, and the anterior vaginal wall is closed with absorbable suture in a running fashion. After completion of the repair, indigo carmine or methylene blue is administered and cystoscopy is performed to inspect the bladder for iatrogenic injury and to visualize ureteral patency. Vaginal packing may be used to cover the surgical area and assist with hemostasis.

Results. In earlier studies, the reported cure rate of anterior colporrhaphy approached 100% (Table 83-3). In a large, retrospective study looking at 299 patients with anterior vaginal wall prolapse, Porges and Smilen reported a recurrence rate of only 3%, with a mean follow-up of 31 months (Porges and Smilen, 1994). In a prospective, randomized trial between Burch colposuspension and anterior colporrhaphy, Colombo and colleagues reported a recurrence rate again of only 3% in the 33 patients who underwent anterior colporrhaphy, with a mean follow-up of 5 years (Colombo et al, 2000). In a retrospective secondary analysis study comparing anterior colporrhaphy alone with anterior colporrhaphy plus sling, anterior prolapse was noted in 42% of those who underwent anterior colporrhaphy alone, versus 19% in those who had concomitant sling (Goldberg et al, 2001). It is interesting to note that in series comparing anterior colporrhaphy with augmented

repairs, reported recurrence rates for standard anterior colporrhaphy approach 40%, significantly higher than recurrence rates noted earlier (Table 83-4). Part of this discrepancy can be accounted for by the use of alternative and composite outcome measures in these studies. Sand and colleagues reported on 161 women randomized to anterior colporrhaphy with polyglactin 910 (Vicryl) suture alone or anterior colporrhaphy with a free Vicryl mesh inlay placed under the trigone after plication of the pubocervical fascia (Sand et al, 2001). At 1 year, the women randomized to Vicryl mesh inlay had a failure rate of 25% compared with 43% in women who underwent plication with suture alone ($P = .02$). Weber and colleagues compared anterior colporrhaphy reinforced with Vicryl mesh versus traditional plication without tension using polydioxanone suture and "ultralateral" plication using both polydioxanone suture and tension (Weber et al, 2001). In this study, 114 women with symptomatic cystoceles (mostly stages 2 and 3 on the POP-Q) were randomized among the three groups. With a mean follow-up of 23 months, there was no significant difference in failure rate (defined as stage 2 or greater on the POP-Q) among the three groups. The failure rate was 30% in those who underwent tradi-

tional plication, 46% in those who underwent ultralateral plication, and 42% in those who underwent traditional plication augmented with Vicryl mesh. Unfortunately, the study did not recruit enough women to achieve statistical power to detect differences among the groups. It is interesting to note that an earlier paper by the same author stated that anterior vaginal wall prolapse recurs after standard anterior colporrhaphy in only 20% of patients (Weber and Walters, 1997). The Sand and Weber trials are not similar enough to allow meta-analysis. As noted earlier, recent re-evaluation of the Weber dataset from 2001 revealed significantly better outcomes when defining failure as recurrent prolapse beyond the hymen (Chmielewski et al, 2011). Failure rates at 1 year were 11% in the traditional plication group, 23% in the ultralateral group, and 9% in the mesh augmented group, adding up to a combined objective recurrence rate of 12% with no statistically significant difference among groups. Before the re-evaluation of these data, concern over high recurrence rates and lack of durability with anterior colporrhaphy, especially in women with moderate- or high-grade prolapse, led investigators to explore augmented repairs using biologic and nonbiologic sources.

AC, anterior colporrhaphy; FDR, four defect repair; NR, not reported; POP-Q, Pelvic Organ Prolapse Quantification System; SEAPI-QMM, stress-related leak (S), emptying ability (E), anatomy (female) (A), protection (P), inhibition (I), quality of life (Q), mobility (M), and mental status (M); SIS, small intestine submucosa.

Complications. Reported complications from anterior colporrhaphy include de novo or occult stress urinary incontinence (SUI), de novo overactive bladder symptoms, postoperative urinary retention, incomplete bladder emptying, significant bleeding exceeding 350 mL, wound infection, bladder or ureteral injuries, vesicovaginal fistula, vaginal shortening, epithelial inclusion cyst, and dyspareunia. **De novo detrusor overactivity** can occur in 5% to 7% of patients after standard colporrhaphy (Raz et al, 1991). Yet, **preexisting detrusor overactivity** has been reported to resolve in up to 63% of patients after surgical repair of POP (Nguyen and Bhatia, 2001). Urinary retention usually occurs in cases during which a

concomitant anti-incontinence procedure was performed; however, retention or incomplete emptying may occur in the absence of anti-incontinence surgery and may be the result of neurologic trauma and impaired bladder contractility from the plication procedure itself. In most instances, the retention resolves after a brief period of clean intermittent catheterization (CIC). If the retention persists and the patient had a concomitant anti-incontinence procedure, sling incision or urethrolisis may be required. When impaired bladder emptying is the result of preexisting hypocontractility, the patient may require chronic CIC, neuromodulation, or as a last resort suprapubic tube drainage.

Bleeding during anterior colporrhaphy is usually caused by both the high vascularity of the vagina and the venous complex beneath the inferior pubic bone. During anterior colporrhaphy, problematic bleeding can occur if the dissection is carried out in the wrong plane. The vaginal wall should be dissected off of the pubocervical fascia directly on its white shiny surface. In patients undergoing repeat anterior colporrhaphy, scarring will often obscure the correct dissection plane. Accordingly, these patients are at higher risk for bleeding.

Bladder or ureteral injuries are rare during standard anterior colporrhaphy. Bladder injuries can occur when perforating into the retropubic space or during dissection of the vaginal flaps, especially in women with atrophic tissue. Ensuring bladder drainage before perforating the endopelvic fascia may reduce this. Should an inadvertent bladder injury occur, a two-layer closure should be performed with absorbable suture. If the patient has a history of pelvic irradiation or if the repair quality seems tenuous, a labial fat pad interposition should be considered to prevent vesicovaginal fistula formation (Kreder, 1993). Cystoscopy after the administration of indigo carmine should be routinely performed with every anterior colporrhaphy. If blue-stained urine is not seen effluxing from both ureteric orifices, ureteral catheterization, retrograde pyelography, or takedown of the plication sutures should be performed. In some cases the ureter is patent and an alternative reason including inadequate fluid resuscitation or ureteral kinking will explain the lack of efflux. Appropriate steps must be taken to ensure ureteral patency if the ureter cannot be catheterized.

Procedures for Lateral and Combined Defects

Vaginal Paravaginal Repair. In his first description of a vaginal paravaginal repair, George White described a cystocele repair that involved suturing the lateral sulci of the vagina to the white line of the pelvic fascia (White, 1909). White believed that the cause of a cystocele was weakness of the lateral vaginal attachments to the ATFP. As Kelly's anterior colporrhaphy became the primary technique of cystocele repair for the next 70 years, White's concept fell into disfavor. In 1976, Richardson reintroduced the paravaginal defect repair (PVdR), but he described the technique using an abdominal approach (Richardson et al, 1976). Regardless of the approach, the goal of a paravaginal repair is to repair a lateral compartment defect by reattaching the pubocervical fascia to the ATFP. A vaginal paravaginal repair may be combined with anterior colporrhaphy in patients with combined lateral and central defects.

Technique (Fig. 83-14). A midline vertical incision is made through the anterior vaginal wall from the bladder neck to the vaginal apex. After the vaginal wall is sharply dissected off the attenuated pubocervical fascia and bladder, the dissection is carried laterally to the pelvic sidewall. Blunt dissection can be used to facilitate this. Access to the pelvic sidewall is achieved by continued lateral dissection and perforation of the endopelvic fascia. On entry into the retropubic space, palpation is used to identify the ATFP as it courses from the ischial spine to the inferior aspect of the pubic ramus. Deep, lighted retractors may be useful to facilitate exposure. With the bladder retracted medially, five to seven interrupted nonabsorbable sutures are placed at 1-cm intervals through the ATFP. A Capiro Suture Capturing Device (Boston Scientific) needle driver may expedite placement of these sutures. These sutures are then passed through the lateral edge of the detached pubocervical fascia. No sutures should be tied until all are placed on either one side or both sides (if bilateral defects). At this point, if indicated, central defect plication sutures may be placed to complete a combined repair. As with anterior colporrhaphy, cystoscopy must be performed to confirm ureteral patency and the absence of intravesical sutures. The vaginal wall is trimmed judiciously, if needed, and closed with a 2-0 absorbable suture. Vaginal packing is placed at the end of the case.

Results (see Table 83-3). Shull and colleagues reported successful repair without any evidence of prolapse in 41 patients (73%) after a mean follow-up of 1.6 years (Shull et al, 1994). Of the 15 recur-

rences, only 4 patients developed prolapse to or through the hymen, and in these 4 the prolapse was less than what was noted preoperatively. Grody and colleagues reported a 99% success rate in 72 patients 0.5 to 3 years after vaginal paravaginal repair (Grody et al, 1995). Elkins and colleagues reported an 8% lateral cystocele recurrence rate and a 22% central cystocele recurrence rate 0.5 to 3 years after vaginal paravaginal repair in 25 patients with grade 3 or greater anterior wall vaginal prolapse (Elkins et al, 2000). Midline central defects were common, leading surgeons to perform joint repairs with an anterior colporrhaphy. Young and colleagues retrospectively evaluated 100 patients with symptomatic grade 2 to 4 combined central and lateral cystoceles (Young et al, 2001). All 100 patients underwent both vaginal paravaginal repair and concomitant anterior colporrhaphy. With a mean follow-up of 11 months, the lateral cystocele recurrence rate was only 2% and the central cystocele recurrence rate was 22%. Mallipedi and colleagues reported a 3% central cystocele recurrence 20 months after vaginal paravaginal repair in 35 patients with grade 2 to 4 anterior vaginal wall prolapse (Mallipedi et al, 2001). Of the 21 patients with concomitant SUI, 12 (57%) had persistent SUI after the paravaginal repair. The paravaginal repair, like standard anterior colporrhaphy, is ineffective in the treatment of SUI.

A retrospective analysis of patients undergoing anterior colporrhaphy alone versus anterior colporrhaphy plus PVdR reported no statistically significant differences between the groups in either subjective or objective outcome measures (Morse et al, 2007).

Although complications after vaginal paravaginal repair are infrequent, they are significant. Young reported 21 major complications, including 3 major intraoperative hemorrhagic complications (Young et al, 2001). Two patients developed lower extremity neuropathy; one was in the lithotomy position for a prolonged period of time. Elkins reported a transfusion rate of 12% (Elkins et al, 2000). Mallipedi reported 2 patients with vaginal abscesses that required drainage, 1 patient with retropubic hematoma who required re-exploration, and 1 patient with bilateral ureteral obstruction, which resolved after takedown of the repair and suture replacement (Mallipedi et al, 2001).

The vaginal paravaginal repair as described is technically more challenging than the standard anterior colporrhaphy. Complication rates are higher and usually more serious. In addition, the conventional vaginal paravaginal repair relies on suture placement through weakened pubocervical fascia. To compensate for these factors, most surgeons describe transvaginal correction of lateral defects using placement of grafts, which are attached to the pelvic sidewalls bilaterally.

Anterior Compartment Repairs Using Grafts

Technique. The incision and dissection into the retropubic space are carried out in a similar manner as in the vaginal paravaginal repair. Once access to the pelvic sidewall is achieved, the bladder is retracted medially, and two or more sutures (permanent or delayed absorbable) are placed into the ATFP and/or obturator internus fascia, which will serve as adequate lateral fixation for the graft. The graft material may also be anchored distally to the bladder neck and apically to the cervix, bladder, or vaginal wall. A Capiro Suture Capturing Device (Boston Scientific) may expedite placement of these sutures (Fig. 83-15). Before the graft is fashioned, it is useful to estimate the distance between the proximal and distal ipsilateral sutures and the distance between the sutures on each side. These measurements serve to determine the dimensions of the graft material, which is trimmed to size. At this point, central plication sutures may be performed. The previously placed pelvic sidewall sutures are then brought out to the corresponding locations on the graft. The sutures are then tied, securing the graft to the pelvic sidewall. It is useful to leave the sutures long until after cystoscopy confirms patency of the ureters. The vaginal wall is judiciously trimmed, if needed, and closed with a 2-0 absorbable suture. Vaginal packing is placed at the end of the case. Graft-augmented cystocele repairs can also be performed using a vaginal mesh kit. The technical components vary with each proprietary kit but in general involve

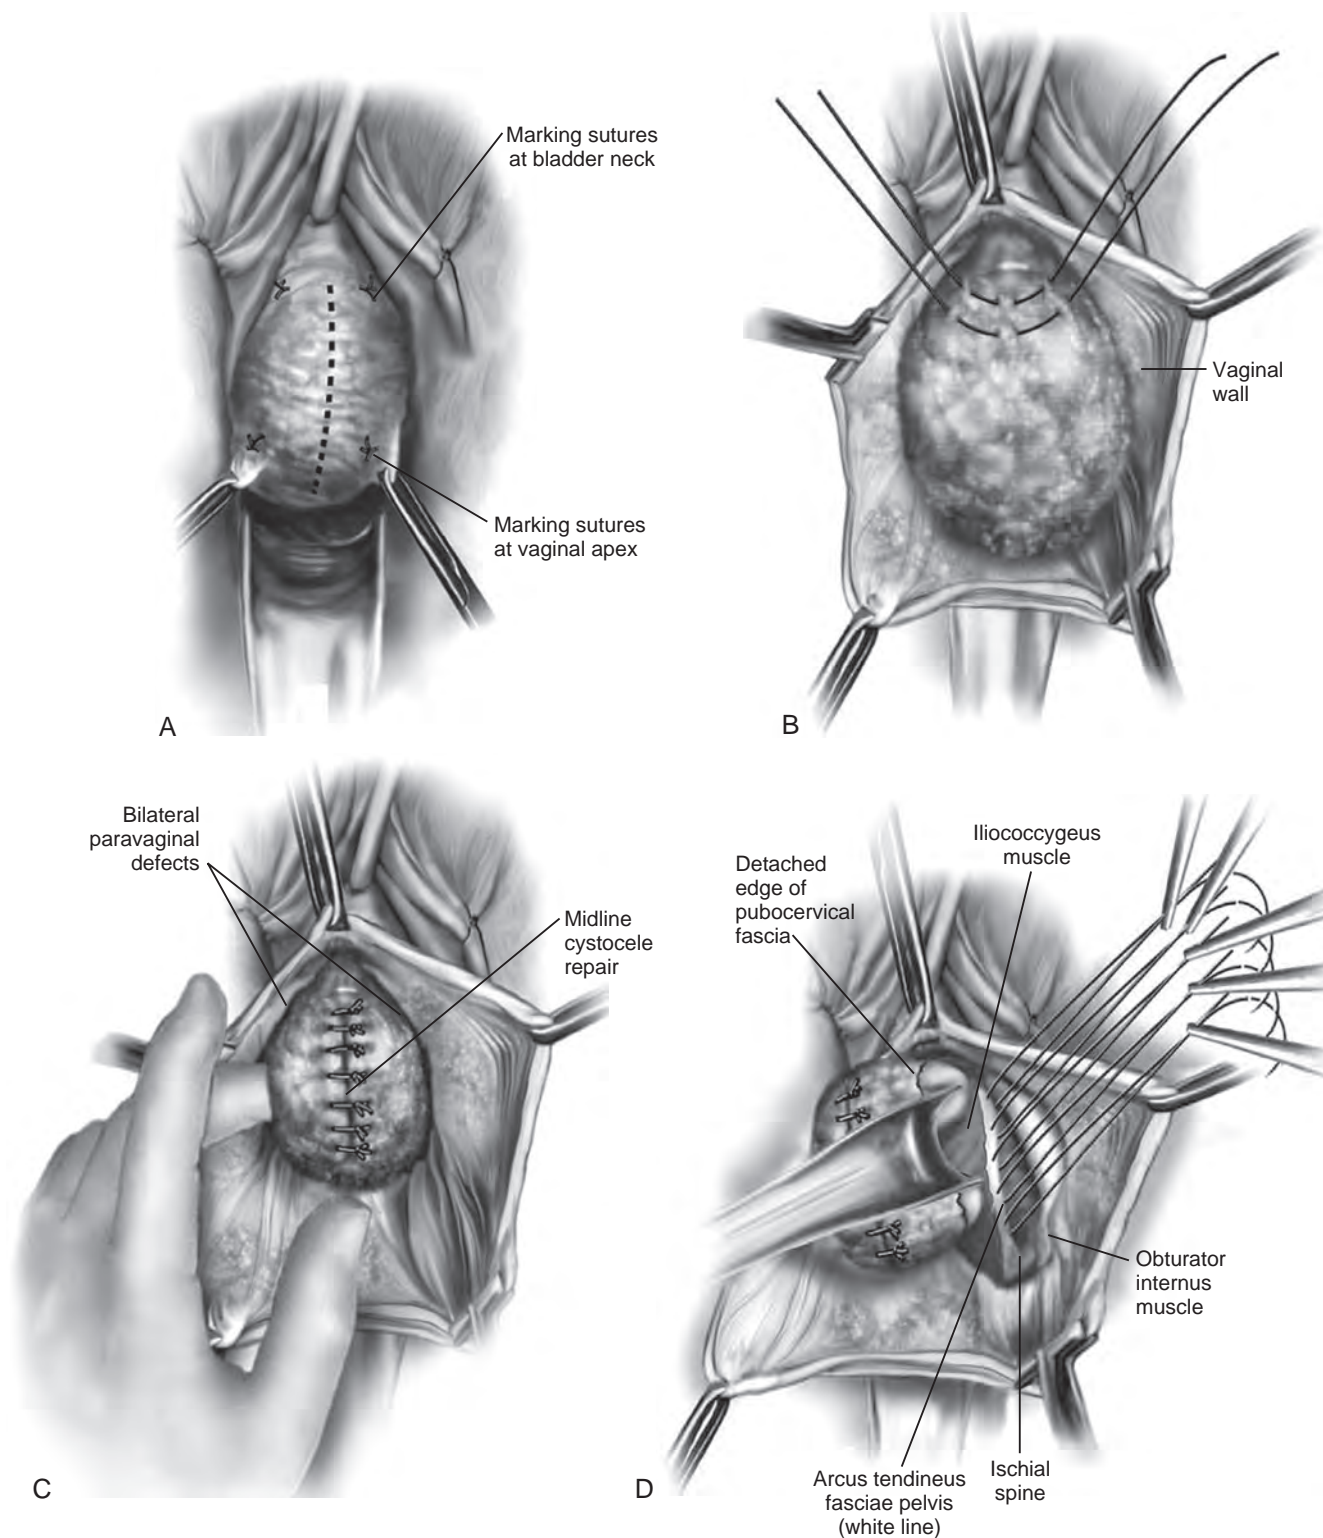

Figure 83-14. Vaginal paravaginal repair. A, Unopened anterior vaginal wall with marking sutures placed at anatomic level of bladder neck and vaginal apex. B, Anterior vaginal wall opened via a midline incision. Sutures placed for midline cystocele repair. C, Midline cystocele repair completed. Bilateral paravaginal defects identified. D, Bladder retracted medially to expose lateral pelvic sidewall. Permanent sutures have been passed through the white line.

fixation of the graft to the pelvic sidewalls using different attachment mechanisms.

Results

Polypropylene Mesh (see [Table 83-4](#)). In 1996, Julian reported a prospective case-control study in which Marlex mesh overlay was found to eliminate prolapse recurrence, whereas 33% of patients who underwent anterior colporrhaphy alone experienced recurrence. Marlex mesh was associated with mesh erosion in 25% of patients ([Julian, 1996](#)). A retrospective review of Marlex mesh in 142 women with a mean follow-up of 3.2 years found no recurrence of prolapse and a 2% mesh erosion rate ([Flood et al, 1998](#)). Nicita described the use of polypropylene mesh for the treatment of anterior vaginal wall prolapse ([Nicita, 1998](#)). He sutured the mesh to the anterior aspect of the ATFP on each side using 3-0 Prolene sutures. With 2 years of follow-up, only 3 of the 44 patients (7%) had prolapse recurrence. The only patient who developed dyspareunia had vaginal mesh extrusion (exposure), and this was managed with mesh trimming and vaginal closure. Several subsequent studies using polypropylene mesh reported variable success ranging from 76% to 98% ([de Tayrac et al, 2002, 2005, 2006b; Salvatore et al, 2002; Cervigni et al, 2008; Sivaslioglu et al, 2008](#)). [De Tayrac and colleagues in 2002](#) described placement of polypropylene mesh (Gynemesh, Ethicon) into the retropubic space in a tension-free fashion without suture fixation ([de Tayrac et al, 2002](#)). The lateral extensions of the mesh were placed in contact with the ATFP and

anchored with a transobturator approach. A total of 48 women with grade 3 and 4 cystoceles underwent this procedure. After a mean follow-up of 18 months, the authors reported an anatomic success rate of 97.9%. Vaginal mesh extrusion was noted in 8.3%. In a subsequent series with 87 women and with 24 months of follow-up, de Tayrac again used Gynemesh and found that 77 women (88.5%) were cured of their symptomatic anterior vaginal wall prolapse, defined as POP-Q stage 0 or 1 (de Tayrac et al, 2005). Of the 7 patients with recurrent cystoceles, 5 were asymptomatic. Vaginal mesh extrusion was again noted in 8.3%, and the de novo dyspareunia rate was 16.7%.

In a prospective study of 98 patients with stage 3 or 4 cystoceles, Rodríguez and colleagues attached a 5- × 5-cm piece of polypropylene mesh to the obturator internus fascia using 2-0 polyglactin suture after repair of the central defect with horizontal mattress sutures of 3-0 polyglactin (Rodríguez et al, 2005) (Fig. 83-16). All patients underwent a distal urethral polypropylene sling regardless of any SUI symptoms. The researchers reported an 85% anatomic success rate, defined as stage 0 or 1. Three patients who did not report SUI before the procedure developed mild de novo SUI after the procedure. Overall QoL associated with genitourinary symptoms improved from 4.7 (unhappy) to 1 (pleased) ($P < .005$).

Carey and colleagues reported on 139 women randomized to mesh augmented anterior and posterior repair versus anterior and posterior colporrhaphy (Carey et al, 2009). No statistical difference in outcomes was noted with either objective or subjective measures. De novo dyspareunia rates were equal in the groups. Vaginal mesh exposure occurred in 5.6%.

Nguyen and colleagues used the armed Perigee device (American Medical Systems, Minnetonka, MN) in their randomized controlled trial of 76 women (Nguyen and Burchette, 2008). A marked improvement in objective anatomic outcomes at 1 year was noted compared with women who underwent anterior colporrhaphy (87% vs. 55%, $P < .05$). QoL, sexual activity, and dyspareunia rates were similar in the groups. There was a 5% mesh erosion rate and a 2% rate of transient leg pain that diminished by 8 weeks.

Figure 83-16. Anterior compartment repair with polypropylene mesh graft. Polypropylene mesh is anchored to the uterosacral ligament at the bladder base, laterally to the obturator fascia and distally to the bladder neck using 2-0 polyglactin suture. (From Rodríguez LV, Bukkapatnam R, Shah SM, et al. Transvaginal paravaginal repair of high-grade cystocele central and lateral defects with concomitant suburethral sling: report of early results, outcomes, and patient satisfaction with a new technique. *Urology* 2005;66[Suppl. 5A]:57-65.)

In a randomized controlled trial of 202 women with anterior vaginal wall prolapse, Nieminen and colleagues compared anterior colporrhaphy ($n = 97$) with the same procedure reinforced with low-weight polypropylene mesh ($n = 105$) (Hiltunen et al, 2007; Nieminen et al, 2010). After 3 years of follow-up, the addition of the polypropylene mesh to the anterior repair did statistically decrease the risk of recurrent stage 2 or greater anterior prolapse. Recurrence was noted in 14 of 105 women in the mesh group versus 40 of 97 women in the group with no graft ($P < .0001$). However, there was no statistically significant difference in symptomatic outcomes (pelvic pressure, vaginal bulge, or difficulty with bladder emptying) between the groups. Importantly, 18 patients in the mesh group (17.3%) had vaginal extrusion of the mesh; however, the use of mesh was not associated with an increase in dyspareunia.

Altman and colleagues reported on the multicenter randomized trial of the armed Gynecare Prolift device (Ethicon; not currently available in the United States) versus anterior colporrhaphy (Altman et al, 2011). According to a composite measure of both anatomic reduction and lack of bulge symptoms at 1 year, 61% of women in the Prolift group and 35% in the anterior colporrhaphy group achieved success. Subjective success was reported in 75% of the Prolift group and 62% of the anterior colporrhaphy group ($P = .008$). Prolift was associated with de novo SUI (12.3% vs. 6.0%), dyspareunia (7.3% vs. 2%), and a reoperation rate of 6% versus 0.5%. The mesh exposure rate was 11.5%.

Vollebregt and colleagues reported on a multicenter randomized trial of the armed Avaulta device (C.R. Bard, Murray Hill, NJ; not available in the United States) versus anterior colporrhaphy (Vollebregt et al, 2011). At 1 year, objective success was 91% in the Avaulta group versus 41% in the anterior colporrhaphy group. No subjective difference was noted in this study. The mesh exposure rate was only 4% and was felt to be the result of not performing a concomitant hysterectomy and/or collagen coating of the Avaulta mesh.

A 2013 Cochrane review reported that standard anterior repairs were associated with more postoperative anterior wall prolapse than polypropylene mesh repairs (relative risk [RR] 3.15; 95% confidence interval [CI] 2.50 to 3.96) and a higher rate of subjective failure (28% vs. 18%, RR 1.62, 95% CI 1.22 to 2.14) (Maher et al, 2013b). Further prolapse surgery was not more common in the anterior colporrhaphy group, and no differences in QoL data or de novo dyspareunia were identified. De novo SUI was greater in the mesh repair group (RR 1.8, 95% CI 1.0 to 3.1). The cumulative mesh erosion rate was 11.4%, and the reoperation rate to correct the erosion was 6.8%.

Alteration of the vaginal axis with compensatory prolapse in an untreated compartment has been well reported. Development of apical and/or posterior prolapse (stage 2 or greater) after an anterior repair with Prolift was seen in 46% of 150 women (Withagen et al, 2010). Pooled analysis of two studies that reported de novo prolapse after anterior repair (Nieminen et al, 2010; Vollebregt et al, 2011) showed a lower rate after anterior colporrhaphy versus anterior mesh repair (9.5% vs. 17.7%, RR 0.49, 95% CI 0.24 to 0.97).

Cadaveric Fascia (Table 83-5). Cadaveric fascia lata with or without pubovaginal sling has shown efficacy rates of 81% to 100% for the treatment of anterior vaginal wall prolapse (Kobashi et al, 2000; Groutz et al, 2001; Powell et al, 2004; Frederick and Leach, 2005). Kobashi and colleagues first described the cadaveric prolapse repair and sling procedure (CaPS) as combined treatment of both symptomatic cystocele and SUI (Kobashi et al, 2000). The procedure was performed transvaginally using a 6- × 8-cm piece of cadaveric fascia lata and bone anchors. Groutz and colleagues treated 21 women with cadaveric fascia lata anchored to the ATFP bilaterally and the cardinal and uterosacral ligaments apically (Groutz et al, 2001) (Fig. 83-17). In a larger study ($n = 251$) with a mean follow-up of 2 years after CaPS, Frederick and Leach noted a symptomatic cystocele recurrence rate of only 7% (Frederick and Leach, 2005). The cured or dry rate for SUI was only 56%, with most of the failures occurring beyond 1 year; the authors questioned the long-term efficacy of the sling portion of the procedure.

TABLE 83-5 Outcomes of Transvaginal Uterosacral Ligament Repairs

POP-Q, Pelvic Organ Prolapse Quantification System.

Figure 83-17. Anterior compartment repair with cadaveric fascia graft. Cadaveric fascia patch was tailored appropriately. Typically a 5- × 7-cm patch is more than adequate. (From Groutz A, Chaikin DC, Theusen E, et al. Use of cadaveric solvent-dehydrated fascia lata for cystocele repair—preliminary results. *Urology* 2001;58:179-83.)

Gandhi and colleagues published a prospective randomized controlled trial ($N = 162$) comparing ultralateral anterior colporrhaphy with 0 polyglactin suture versus the same colporrhaphy reinforced with cadaveric fascia lata in women with grade 2 or higher anterior vaginal wall prolapse (Gandhi et al, 2005). The addition of the fascia lata patch to the anterior repair did not statistically decrease the risk of recurrent prolapse ($P = .23$). Of the 39 patients with recurrent prolapse, 26 (67%) were asymptomatic. Concomitant transvaginal Cooper ligament sling was associated with a significant decrease in recurrent prolapse (odds ratio [OR] 0.015, $P < .0001$).

Cadaveric dermis has been used in the treatment of anterior compartment prolapse with efficacy of 42% to 84% at 2 years of follow-up (Chung et al, 2002; Clemons et al, 2003; Behnia-Willison et al, 2007). Chung and colleagues described anchoring the proximal portion of the 3- × 7-cm graft to the uterosacral-cardinal ligament complex, and the distal portion was used as the sling (Chung et al, 2002). Patients with lateral and paravaginal defects were excluded. Clemons and colleagues described a vaginal paravaginal repair using cadaveric dermis in 33 women with recurrent stage 2 or with primary or recurrent POP-Q stage 3 or 4 cystoceles (Clemons et al, 2003). The 3- × 7-cm graft was positioned over the bladder base and secured to the ATRP with four sutures of 2-0 braided permanent polyester bilaterally.

Figure 83-18. Anterior compartment repair with porcine dermis graft. Three pairs of delayed absorbable sutures are inserted into the arcus tendineus fasciae pelvis and into the porcine dermis patch. (From Gomelsky A, Rudy DC, Dmochowski RR. Porcine dermis interposition graft for repair of high grade anterior compartment defects with or without concomitant pelvic organ procedures. *J Urol* 2004;171:1581-4.)

Porcine Dermis (see Table 83-4). The majority of clinical experience in the use of xenografts for POP has been with porcine dermis. Pelvicol (C.R. Bard) is acellular cross-linked porcine dermis (Chen et al, 2007). Gomelsky and colleagues reported favorable, durable outcomes using a 6- × 8-cm piece of porcine dermis sutured laterally to the ATFP to correct high-grade cystoceles (Gomelsky et al, 2004) (Fig. 83-18). In a retrospective review of 70 patients, 61 (87%) had no cystocele recurrence after a mean follow-up of 24 months. Of the 9 patients (13%) with recurrent cystoceles, none were symptomatic. One patient had superficial vaginal wound separation, which was treated with conservative measures.

Meschia and colleagues published a prospective randomized controlled trial comparing anterior colporrhaphy with 0 polyglactin suture (n = 103) versus the same colporrhaphy reinforced with a 4- × 7-cm piece of Pelvicol (n = 98) in women with stage 2 or higher anterior vaginal wall prolapse as defined by POP-Q (Meschia et al, 2007). After 1 year of follow-up, treatment in the women randomized to receive the Pelvicol graft failed 7% of the time compared with the 19% failure rate in those women who underwent the anterior colporrhaphy alone (P = .019). One patient who received the Pelvicol graft had vaginal extrusion of the material 1 month after surgery. There were no differences between the two groups in the incidence of postoperative dyspareunia.

Handel compared two different grafts (polypropylene mesh [n = 25] and porcine dermis [n = 56]) versus traditional anterior colporrhaphy with suture alone (n = 18) (Handel et al, 2007). For

patients undergoing repair with a graft, it was anchored to the levator fascia bilaterally and to the uterosacral-cardinal ligament complex apically. With a mean follow-up of 13.5 months, there was no significant difference in failure rate (defined as grade 2 or greater) among the three groups. There was a 21% rate of vaginal extrusion of the porcine dermis.

SIS has also been compared with colporrhaphy alone in a randomized controlled trial (N = 57) (Feldner et al, 2010). The SIS group had 86.2% anatomic cure versus 59.3% in the colporrhaphy group (P = .03). Both operations significantly improved QoL without differences noted between the groups. No infections or erosion were discovered.

Biologics versus Mesh. Natale and colleagues performed a prospective randomized trial (N = 190) comparing polypropylene mesh (Gynecare) with porcine dermis (Pelvicol) in women with recurrent anterior wall prolapse (Natale et al, 2009). Objective cure was 71.9% in the mesh group and 56.4% in the porcine dermis group (P = .06). No difference in subjective cure was noted; however, a better impact of surgery on sexual function was reported in the porcine group. Mesh erosion occurred in 6.3% of the mesh group, and no erosions were seen with porcine dermis (P = .03).

Menefee and colleagues performed a randomized clinical trial comparing anterior colporrhaphy, vaginal paravaginal repair using porcine dermis, and vaginal paravaginal repair with self-styled polypropylene mesh (Menefee et al, 2011). Two-year follow-up was completed on 78 of 99 (79%) enrolled patients. Mesh repairs had the lowest anatomic failure rate (18%), followed by porcine dermis (46%, P = .015), then colporrhaphy (58%, P = .002). Subjective improvement in prolapse and voiding scores were similar, and composite failure was no different among groups (4% mesh, 12% porcine, 13% colporrhaphy). Mesh erosion was reported in 14% and porcine erosions in 4% (P = .413).

A 2013 Cochrane review concluded that objective failure rates were higher with colporrhaphy alone than with the use of biologic graft (RR 2.08, 95% CI 1.08 to 4.01) (Maher et al, 2013b). Subjective cure rates were not different between groups.

Complications. Vaginal exposure (extrusion) has been reported in anterior compartment prolapse repair with most materials. In 21 trials on mesh-augmented repairs summarized in a Cochrane review, the mean mesh erosion rate was 11.4% (64 of 563), with 6.8% (32 of 470) undergoing surgical intervention for the erosion (Maher et al, 2013b). Reoperation rates for prolapse, QoL measures, and de novo dyspareunia were no different in women undergoing native tissue repair versus mesh repair (Maher et al, 2013b). Dyspareunia has also been reported in 3.1% to 19% of patients with anterior colporrhaphy (Dwyer and O'Reilly, 2004; Yan et al, 2004; Milani et al, 2005). Blood loss (mean difference [MD] 64 mL, 95% CI 48 to 81), operating time (MD 19 min, 95% CI 16 to 21), recurrences in apical or posterior compartment (RR 1.9, 95% CI 1.0 to 3.4), and de novo SUI (RR 1.8, 95% CI 1.0 to 3.1) were significantly higher with mesh repair than with native tissue repair.

The Society of Urodynamics, Female Pelvic Medicine and Urogenital Reconstruction (SUFU) released a position statement in July 2011 in response to the FDA safety communication regarding the use of mesh for prolapse surgery. "The contemporary incorporation of mesh into surgical repair has pros and cons. Mesh may improve long-term anatomic results of surgery as compared with nonmesh repairs for some types of prolapse but is also associated with risks to the patient including vaginal extrusion, erosion, sexual dysfunction, urinary tract injury, pain, and other complications. However, it is important to recognize that many of these complications are not unique to mesh surgeries and are known to occur with non mesh procedures as well." SUFU concluded that it is not feasible "to make universal recommendations for or against the utilization of vaginal mesh based on the scientific evidence base currently available. There exists a population of patients for whom mesh has potential benefit. For these individuals, it may be appropriate to consider the implantation of transvaginal mesh if the potential risks and benefits are understood by the surgeon and the patient" (SUFU, 2011).

Other Procedures to Correct Anterior Compartment Defects

Abdominal Paravaginal Repair

Technique (Fig. 83-19). Positioning and preparation of the patient to allow both abdominal and vaginal access initiate the repair. The bladder is drained. The retropubic space is entered through either a low midline or transverse incision. In addition, this may be accomplished laparoscopically. The bladder neck, symphysis pubis, endopelvic fascia, ATRP, and obturator fascia should all be clearly identified. The site of normal vaginal attachment on the pelvic sidewall from the interior aspect of the superior pubic ramus to the ischial spine is then identified. The surgeon's nondominant hand is placed into the vagina and used to elevate the lateral superior vaginal sulcus to its site of normal attachment along the course of the ATRP. With the bladder retracted medially, four to six interrupted nonabsorbable sutures are placed at 1-cm intervals through the ATRP, extending from the ischial spine to the pubic bone. These sutures are then placed in the appropriate location in the lateral

wall of the vagina. Care is taken to avoid paravaginal veins, which commonly course through this area. Elevating the vagina to its normal anatomic position to localize suture placement site may facilitate vaginal suture placement. After the sutures are tied, cystoscopy must be performed to confirm ureteral patency and the absence of intravesical sutures. The incision is closed and the catheter is left indwelling.

Results (see Table 83-4). Richardson popularized the abdominal PVdR (Richardson et al, 1976). In a retrospective study of 233 patients with follow-up spanning 2 to 8 years, Richardson reported an anatomic cure rate of 95% (Richardson et al, 1981). Of these patients, 53 (23%) had previously undergone 1 or more anterior vaginal wall prolapse repairs. No patient required transfusion. Eighty-eight percent of the women with preoperative SUI were cured after abdominal paravaginal repair.

Other authors published the results of case series that demonstrated similar encouraging anatomic results and SUI cure rates of 85% to 97% after abdominal paravaginal repair (Baden and Walker,

Figure 83-19. A-C, Abdominal paravaginal repair. Paravaginal defect repair as viewed from the retropubic space: approximation of the pubocervical fascia medially to the arcus tendineus fasciae pelvis laterally with 2-0 braided nonabsorbable suture. Note the vertical orientation of the vaginal vessels in relation to the transverse orientation of the bladder vessels. (From Baggish M, Karram M. Atlas of pelvic anatomy and gynecologic surgery. 3rd ed. Philadelphia: Saunders; 2010.)

1987; Shull and Baden, 1989). However, evidence over the last 15 years suggests that abdominal PVdR is not as effective as either the Burch colposuspension or suburethral sling for the treatment of SUI. In 2000, Colombo and colleagues published the results of a randomized trial comparing PVdR versus Burch colposuspension for the treatment of SUI in 18 patients (Colombo et al, 2000). With a mean follow-up of 2.2 years, the objective (urodynamic) cure rates were 100% for Burch colposuspension and 61% for abdominal PVdR. Colombo found that Burch colposuspension increased the functional urethral length and pressure-transmission ratio in the proximal urethra, whereas the abdominal paravaginal repair did not. Bruce and colleagues examined the abdominal PVdR in the treatment of women with both lateral cystocele and symptomatic SUI (Bruce et al, 1999). In this retrospective cohort of 52 patients, half underwent abdominal PVdR and half underwent abdominal PVdR with pubovaginal sling using rectus fascia. All the patients who underwent concomitant sling procedures had intrinsic sphincter deficiency (ISD). With a mean follow-up of 17 months, 4 patients (8%) had recurrent cystocele, 3 patients developed vault prolapse, and 1 patient developed an enterocele. Thus, the overall prolapse cure rate was 85%. Finally, the overall cure rate for SUI was 72% in the group that underwent PVdR alone and 85% in the group that underwent PVdR and pubovaginal sling procedures.

Anterior Compartment Repair with Sling. In patients with high-stage anterior compartment prolapse, the descent may create urethral kinking and urethral compression (Gallentine and Cespedes, 2001) (Fig. 83-20). This compression may prevent leakage of urine despite poor urethral function, thereby unmasking SUI after prolapse correction. Documenting the presence of SUI in patients with the prolapse reduced is helpful in the preoperative planning of women with high-grade anterior compartment prolapse. SUI occurring in presumably continent women after prolapse correction is known as *occult SUI*. It is essential for women with high-stage prolapse to undergo an evaluation with the prolapse reduced in order to identify those at risk for occult SUI. In three prospective studies, POP repair in clinically continent women was shown to result in postoperative SUI in 8.3% to 22% (Stanton et al, 1982; Borstad et al, 1989; Ballert et al, 2009).

To diagnose occult SUI, the prolapse may be reduced with vaginal packing, rectal swabs, a speculum blade, or a pessary. Ghoniem and colleagues used a vaginal pack (formed from two rolled 4 × 4 gauzes) to reduce large cystoceles and found occult SUI

in 69% of the women (Ghoniem et al, 1994). They found that the vaginal pack provided superior visualization of the vesicourethral angle during fluoroscopic urodynamics. Gallentine used gauze packing and a speculum blade to reduce high-stage POP and found occult SUI in at least 50% of the women with high-grade anterior compartment prolapse (Gallentine and Cespedes, 2001). Using a fitted vaginal pessary, Chaikin and colleagues detected occult SUI in 58% of the women (Chaikin et al, 2000). They also noted that none of the women had urethral obstruction after pessary placement. Multiple techniques are used to reduce prolapse, and these methods are not standardized. This has led to variance in the reported incidence of occult SUI (Haessler et al, 2005). Veronikis and colleagues compared prolapse reduction with rectal swabs, a Gellhorn pessary, and a Graves speculum blade (Veronikis et al, 1997). Because prolapse reduction with rectal swabs revealed a significantly lower mid-urethral closure pressure, these authors concluded that the rectal swabs were superior. **Sensitivity and specificity data are lacking with all of the methods used to reduce POP.** Accordingly, no method for prolapse reduction has been proven to be superior.

Performing a concomitant sling procedure at the time of anterior vaginal wall prolapse repair in women without symptoms of SUI or occult SUI remains controversial. Twiss and colleagues recommended a simultaneous anti-incontinence procedure at the time of high-grade POP repair because they contend there is no correlation between the preoperative position of the urethra with any method of cystocele reduction and the ultimate position of the urethra after surgery (Twiss et al, 2007). Thus, they contend that the diagnosis of occult SUI is inconsistent and not reproducible. Consequently, occult SUI could be missed. Other authors argue that potential complications from the placement of a concomitant sling equal the risk of occult SUI and therefore it should be offered as a second-stage procedure in those whose incontinence cannot be demonstrated preoperatively (Ballert et al, 2009). Ballert and colleagues evaluated a protocol to assess the concomitant placement of mid-urethral slings at the time of vaginal prolapse surgery (Ballert et al, 2009). They performed urodynamic testing on 140 women with POP; if SUI was seen, they recommended concomitant sling with prolapse surgery. If no SUI was seen, they repeated the testing with prolapse reduction using a pessary. Again, if occult SUI was demonstrated, they recommended a sling with prolapse surgery. Using this protocol they found an equal risk of intervention as a

Figure 83-20. Urethral kinking caused by large cystocele. Fluorourodynamic study shows a large cystocele before (A) and after (B) Valsalva maneuver was performed. The urethra (arrow) clearly can be seen to “kink off” during the Valsalva maneuver. The patient did demonstrate severe stress urinary incontinence after prolapse reduction. (From Gallentine ML, Cespedes RD. Occult stress urinary incontinence and the effect of vaginal vault prolapsed on abdominal leak point pressures. *Urology* 2001;57:40–4.)

result of obstruction from a mid-urethral sling (8.5%) and intervention for postoperative SUI in a patient without clinical, urodynamic, or occult SUI who did not undergo a concomitant sling procedure (8.3%). Therefore, the risk of intervention resulting from sling obstruction was equal to the risk of intervention resulting from postoperative SUI when no clinical, urodynamic, or occult SUI was present preoperatively and no mid-urethral sling was placed. Because the need to intervene for complications resulting from mid-urethral sling equaled the risk of having to perform a secondary sling procedure, the necessity for secondary surgery in women without SUI after repair of anterior vaginal wall prolapse is not decreased. The risk of intervention in those with clinical symptoms of SUI but no urodynamic or occult SUI was 30%.

It has also been reported that a concomitant suburethral sling may contribute to the long-term success of anterior compartment repairs. Goldberg and colleagues demonstrated a 55% reduction in postoperative cystocele recurrence in patients who underwent a suburethral sling procedure at the time of prolapse repair (Goldberg et al, 2001). Also, Cross and colleagues reported that the support created by the simultaneous placement of a pubovaginal sling in grades 3 and 4 cystoceles was improved (Cross et al, 1997).

The Colpopexy and Urinary Reduction Efforts (CARE) trial was the first large, randomized, controlled trial evaluating a simultaneous anti-incontinence procedure with POP repair (Brubaker et al, 2006). The investigators evaluated 322 patients with stage 2 to 4 POP who underwent abdominal sacrocolpopexy (ASC), of whom 157 were randomized to concomitant Burch colposuspension and 165 were randomized to ASC alone. The addition of a Burch colposuspension to ASC decreased postoperative SUI from 44.1% to 23.6% at 3 months postoperatively. In a subsequent study examining 2-year outcomes in the same group of patients, the authors found that 32% of patients who underwent concomitant Burch colposuspension were incontinent versus 45% of patients who underwent ASC alone (Brubaker et al, 2008). Approximately one third of the women after the Burch procedure still had SUI. The Extended CARE (E-CARE) trial enrolled 213 of the original 322 participants, with 181 completing 5 years of follow-up and 121 completing 7 years (Nygaard et al, 2013). By year 7, the estimated probability of SUI in the urethropepy group was 62%, and 77% in the nonurethropepy group. The time to treatment failure for SUI was longer in the urethropepy group.

Wei and colleagues for the Pelvic Floor Disorders Network reported on 337 women enrolled in the Outcomes Following Vaginal Prolapse Repair and Mid-Urethral Sling (OPUS) trial. Women with stage 2 or higher POP without symptoms of SUI underwent randomization for a concomitant mid-urethral sling or sham at the time of vaginal prolapse surgery. At 12 months, urinary incontinence was present in 27% of sling patients and 43% of sham patients ($P = .002$). Higher rates of adverse events were seen in the sling group (bladder perforation, UTI, bleeding, incomplete bladder emptying; $P \leq .05$ for all). There was no difference noted between groups in patient-reported pelvic floor symptoms (Wei et al, 2012).

In summary, there is no standardization of testing for occult SUI. However, it is clear that all women with advanced-stage anterior compartment prolapse should be screened for the presence of SUI with the prolapse reduced, and consideration should be given to a concomitant anti-incontinence procedure. All women with preoperative symptoms of SUI, occult SUI, or urodynamically proven SUI are at elevated risk of postoperative SUI and should consider a simultaneous anti-incontinence procedure. The risks and benefits of a prophylactic anti-incontinence procedure on continent women should be reviewed with each patient. The current literature supports selective use of an anti-incontinence procedure at the time of POP repair.

Apical Vaginal Compartment

Middle compartment defects involve the vaginal apex. The organs involved in defects of the middle compartment include the uterus, bowel or omentum, and depending on the size, bladder and rectum. The apex remains the cornerstone of vaginal support, and failure

KEY POINTS: ANTERIOR COMPARTMENT REPAIR

- Anterior compartment defects can be central, lateral, or combined. A central defect results from midline separation or attenuation of the pubocervical (perivesical) fascia. A lateral defect results when the pubocervical fascia detaches from the ATFP.
- Most anterior compartment defects have concomitant lateral and/or apical defects; isolated anterior colporrhaphy is not recommended when additional defects are present.
- Anterior compartment prolapse repair does not suspend the vaginal apex. Patients with anterior compartment and apical prolapse need concomitant repairs that address each defect.
- Anatomic results after anterior repair are improved by the addition of both biologic and synthetic grafts. However, graft complications may occur. Subjective results appear unchanged with the addition of biologic grafts but are improved with the addition of synthetic grafts. QoL measures, reoperation for prolapse, and dyspareunia rates are unchanged by the addition of synthetic mesh. The risk-benefit ratio of graft use needs to be thoroughly discussed with the patient.
- Anterior colporrhaphy and paravaginal repairs are both ineffective alone in the treatment of SUI.
- All women with advanced-stage anterior compartment prolapse should be screened for occult SUI with prolapse reduction, and the risks and benefits of a concomitant anti-incontinence procedure should be discussed with the patient.

to ensure apical support at the time of prolapse correction will undoubtedly increase the risk of recurrence exponentially.

McCall highlighted this importance when he described his technique of posterior culdoplasty (McCall, 1957). This technique closed the peritoneal cul-de-sac posteriorly, thereby preventing enterocele formation, and emphasized the importance of apical fixation. In this landmark paper, he described the following technique: "The posterior culdeplasty is a simple procedure which obliterates the redundant cul-de-sac of Douglas by a series of continuous sutures so as to suspend it by the uterosacral ligaments which then are brought together in the midline.... The first suture picks up the left uterosacral ligament about 2 cm above its cut edge. Several bites of redundant sac are then taken at 1-2 cm intervals until the right uterosacral ligament is reached and picked up.... Three external through-and-through sutures of this type are usually inserted, each one higher than the last, so as to be placed through the uterosacral ligaments at intervals between the internal sutures. The highest of these is placed just at the top of the newly supported vagina. It is this suture, which brings the new vaginal vault to the highest possible level thus insuring that the vagina will be as long as possible in each instance. The internal sutures are now tied and the previously herniated cul-de-sac obliterated into a firm, shelflike structure. The external sutures are then tied and the vaginal mucosa snugged against this shelf."

Apical Vaginal Prolapse Repairs

The uterosacral vault suspension preserves the orientation of the vaginal axis in its natural position, thus potentially preventing recurrence of prolapse in other segments (Silva et al, 2006). Several authors have reported breakage of the uterosacral ligaments at specific points rather than an attenuation of the uterosacral-cardinal ligament complex, thus allowing for a more site-specific repair (Jenkins, 1997; Barber et al, 2000; Shull et al, 2000). These findings are in contrast to a histologic assessment of the uterosacral ligaments that calls into question the integrity of this structure for long-term apical support (Cole et al, 2006).

Surgical Anatomy of the Uterosacral Ligaments. The ligament is attached broadly to S1 to S3, variably to S4 (Buller et al, 2001) (Figs. 83-21 and 83-22). It proceeds in a fanlike manner anterolaterally to the cervical os and also onto the proximal portion of the posterior vagina. The ligament can be divided into three portions: the sacral, intermediate, and cervical portions. Beneath the sacral portion of the ligament runs the superior gluteal vein. Although there is great variability in the location of the ureter relative to the ischial spine (Karram et al, 2001), the ureter has been reported to be near the anterior margin of the uterosacral ligament near the cervix. As the ureter courses distally, the distance between the uterosacral ligament and ureter decreases from 4 cm near the sacrum to 0.9 cm near the cervix (Buller et al, 2001). Because of the fibrous tissues of the ureteral sheath, the ureter is subject to kinking from

traction caused by sutures placed in the adjacent tissue (Dwyer and Fattou, 2008). If sutures are placed close to the sacrum, there is a risk of entrapping fibers of the sacral plexus trunk of S1 to S4 (Siddique et al, 2006; Wieslander et al, 2007). This can result in buttock pain, which radiates to the posterior thigh and popliteal fossa. Placing sutures in the intermediate portion of the uterosacral ligament appears to be the optimal site; there are fewer structures to be potentially affected, and it provides a stable point of fixation. There is decreased chance of traction affecting the ureter at this point, because it is farther away from the ureter and its sheath. Placing the sutures from lateral to medial will also minimize accidentally catching either the ureter or its attachments in the stitch (Shull et al, 2000). The intermediate segment can be located 1 cm posterior along the palpable uterosacral ligament at the level of the ischial spine with the uterosacral ligament placed on tension (Buller et al, 2001). An advantage of suspension to the uterosacral ligament is that it minimizes injury to the pudendal and gluteal vessels relative to sacrospinous ligament fixation (SSLF) (Barber et al, 2000).

Technique

High Uterosacral Vaginal Vault Suspension. This procedure starts intraperitoneally (Karram et al, 2001). After hysterectomy, the apex is identified on the vaginal cuff at the 3 and 9 o'clock positions, which represent the attachments of the cardinal and uterosacral ligaments (Shull et al, 1993). It is useful to place stay sutures at these dimples before incision. The vaginal epithelium is dissected away from the peritoneum of the hernia sac. Once the dissection has mobilized the hernia sac from the epithelium to the neck of the sac, it is entered and the sac excised (Fig. 83-23). Laparotomy pads are placed to pack the bowel away. Ischial spines can then be palpated transperitoneally. The uterosacral ligaments will be located posteriorly and medially to the ischial spines. By placing traction to the stay sutures or by placing an Allis clamp at the 5 o'clock and 7 o'clock positions of the apex, the uterosacral ligament will tent and two to four nonabsorbable sutures can be placed through the uterosacral-cardinal ligament complex (Fig. 83-24). The ureters should be located lateral to the uterosacral ligaments; however, it should be noted that depending on the degree of the prolapse, there can be significant variability in their location relative to the edge of the uterosacral ligament (Silva et al, 2006). If there is any question as to their location, temporary stents may be placed to facilitate their palpation. In placing the needles through the uterosacral ligaments, it is important to pass them lateral to medial, exiting away from the ureter to avoid inadvertent inclusion into the tie (Shull et al, 2000). To ensure the proper depth, the suture should be

Figure 83-21. Right hemipelvis: sagittal view. The uterosacral ligament (USL) has been reflected to show subjacent anatomy. (From Buller JL, Thompson JR, Cundiff GW, et al. Uterosacral ligament: description of anatomic relationships to optimize surgical safety. *Obstet Gynecol* 2001;97:873-9.)

Figure 83-22. Right hemipelvis: sagittal view. The peritoneum has been removed and the uterosacral ligament (USL) was left intact to show the proximity of the ureter in this specimen. (From Buller JL, Thompson JR, Cundiff GW, et al. Uterosacral ligament: description of anatomic relationships to optimize surgical safety. *Obstet Gynecol* 2001;97:873-9.)

Figure 83-23. Vaginal enterocele repair. Enterocele sac is identified and opened to reduce its contents. It is then tied in a purse-string suture and the excess is excised. Before closure of the enterocele sac, the peritoneal cavity is entered to access the uterosacral ligament. (From Walters M, Karram M. *Urogynecology and reconstructive pelvic surgery*. 3rd ed. Philadelphia: Mosby; 2006.)

Figure 83-24. To identify the uterosacral ligament, an Allis clamp is placed on the vaginal epithelium at the right apex and pulled straight upward. With the right uterosacral ligament on tension, the uterosacral ligament is visible in the pelvis. A long Allis clamp (arrow) is used to grasp the right uterosacral ligament. (From Baggish M, Karram M. *Atlas of pelvic anatomy and gynecologic surgery*. 3rd ed. Philadelphia: Saunders; 2010.)

passed at the level of the ischial spines. Subsequent sutures are placed proximal to the last. If an anterior colporrhaphy or sling is planned, it may be done at this point. Suspensory sutures in the uterosacral ligaments are then placed in the most apical portions of the pubocervical and rectovaginal fascia. The highest sutures are then sewn to the most medial portions of the pubocervical and rectovaginal fascia. The more distal sutures are placed most laterally in the pubocervical and rectovaginal fascia and passed out of the vaginal epithelium on each side (Fig. 83-25). Cystoscopy with indigo carmine is an essential step after this procedure to confirm ureteral patency, and should be performed before trimming the suture because this will facilitate identification of the sutures if they need to be removed owing to obstruction. If no efflux of urine is seen, the sutures should be removed starting with the most lateral suture of the ipsilateral side. In addition, it is important to perform the cystoscopy after the suture is tied, not just placed (Yazdany et al, 2008). As one ties these suspending sutures, the rectovaginal fascia and pubocervical fascia are brought together at the uterosacral ligament complex, thus resuspending the apex of the vagina and closing the cul-de-sac (Fig. 83-26).

An extraperitoneal approach has also been described (Dwyer and Fatton, 2008). A midline incision is made, depending on concomitant prolapse. The vaginal epithelium is then dissected away from the endopelvic fascia, and the enterocele sac is identified and dissected free of the vault. Dissection is continued laterally until the uterosacral-cardinal ligament complex is identified posterior and medial to the ischial spine. Palpation to tent the uterosacral-cardinal ligament complex is facilitated by placing tension on the

vagina. Use of the Breisky-Navratil retractor to retract the bladder and ureters anteriorly has prevented ureteral obstruction through traction or injury (Fatton et al, 2009). Once the ligaments are identified, the sutures are placed in a similar fashion to the intraperitoneal approach. Cystoscopy and vaginal closure are performed as described previously.

Abdominal Approach to the Uterosacral Ligaments. The uterosacral ligaments may be accessed transabdominally (Lowenstein et al, 2009). This technique begins by elevating the uterus at the time of abdominal hysterectomy. Three permanent sutures are placed in each of the uterosacral ligaments proximal and medial to the ischial spine. They are numbered in the manner described by Shull (Shull et al, 2000) (Fig. 83-27). Once the hysterectomy has been performed and the cuff has been closed, the sutures are placed sequentially through the anterior and posterior leaves of the endopelvic fascia. By reapproximating the anterior and posterior muscularis of the vagina, any potential enterocele defects are closed and the cuff is elevated toward the sacrum, recreating the normal vaginal axis. Cystoscopy is performed after tying the sutures, which are left uncut until efflux of urine is demonstrated. If no urine is seen, the most lateral ipsilateral suture is removed and subsequent sutures are taken down in sequence.

Results. Transvaginal uterosacral ligament suspension has been evaluated primarily through uncontrolled retrospective case series. Table 83-5 summarizes the available literature with a mean objective success of 85% and a range of 48% to 96%. Mean reoperation rate for prolapse from the data in Table 83-5 is 5.8%. In 2010, Margulies and colleagues performed a meta-analysis and documented success based on POP-Q stage in the anterior (81.2%), apical (98.3%), and posterior (87.4%) compartments (Margulies et al, 2010). Less than half the studies in the pooled analysis reported postoperative prolapse symptoms. In those that did, 82% to 100% of patients reported relief. Ureteral kinking or injury was reported in 1% to 11% of cases. Shull and colleagues had the largest reported series of patients who underwent uterosacral ligament suspension (Shull et al, 2000). Of 289 patients who were followed, a majority (87%) had no recurrence of support defect at any site on any postoperative examination. Only 5% of the patients had grade 2 prolapse or greater. The most common site was the anterior compartment, in which 10 patients had grade 2 or 3 defects. One patient required ureteroneocystostomy. Two patients required removal of suspensory sutures. Karram and colleagues reported on 168 patients who underwent uterosacral vaginal vault suspension (Karram et al, 2001). Eighty-nine percent reported satisfaction with the results of the procedure. Ten women (5.5%) underwent subsequent surgery for recurrent prolapse. Seven women experienced a major intraoperative complication, 5 (2.4%) ureteral injuries, 1 small bowel injury, and 1 pelvic abscess requiring diverting colostomy. Silva and colleagues evaluated long-term (5.1 years) anatomic and functional outcomes of high uterosacral vaginal vault suspension (Silva et al, 2006). Surgical failure in one or more compartments occurred in 11 (15.3%) patients; apical recurrence occurred in 2 of 78 patients. Seven patients had de novo postoperative dyspareunia. Patient-reported outcomes indicated improvement in irritative voiding, obstructive voiding, stress incontinence, and overall urinary symptoms compared with preoperative scores.

A randomized controlled trial sponsored by the Pelvic Floor Disorders Network comparing uterosacral ligament suspension versus SSLF has completed enrollment of nearly 400 patients (Barber et al, 2009a). The 2-year follow-up data are not yet available. At the time this was written there were no published results, but the study aims to assess whether pelvic muscle exercises and behavioral changes around the time of apical prolapse surgery affect bladder and bowel symptoms after surgery and the success of the prolapse repair.

Fatton and colleagues examined the results of performing an extraperitoneal bilateral uterosacral vaginal vault suspension ($n = 110$) with a mean follow-up of 2 years (Fatton et al, 2009). Concurrent procedures included anterior colporrhaphy (20%), anterior mesh reinforcement (49%), posterior colporrhaphy (56%), and sling (29%). Recurrence at the apex was noted in 4.6% of patients. Global

Figure 83-25. High uterosacral ligament vaginal vault suspension. Three sutures are placed from lateral to medial in each uterosacral ligament. The sutures are brought through the vaginal muscularis anteriorly (pubocervical fascia) and posteriorly (rectovaginal fascia). (From Walters M, Karram M. *Urogynecology and reconstructive pelvic surgery*. 3rd ed. Philadelphia: Mosby; 2006.)

anatomic success was reported in 85.5%. Mesh exposure occurred in 19.3%, was diagnosed within 6 months in the majority of the patients, and required conservative or minor interventions. The authors concluded that this procedure is effective at restoring apical support while avoiding the morbidity of an intraperitoneal operation.

Sacrospinous Ligament Fixation

SSLF was first described by Richter in 1942 but was not widely used until Nichols reported on the technique (Nichols, 1982). SSLF has been shown to be an effective method to correct apical prolapse

(Cruikshank et al, 2003). This technique is appealing because of its extraperitoneal approach and consistency as a strong structure on which to anchor the apex. Access to the spine was originally achieved from the posterior approach, although dissection from the anterior approach may also be performed via the paravaginal space (Cespedes, 2000; Winkler et al, 2000). The advantages of SSL suspension are success rates comparable to those of abdominal procedures (Brown et al, 1989; Imparato et al, 1992), ability to repair concomitant pelvic floor defects, absence of a laparotomy (Morley and DeLancey, 1988), shorter hospital stay (Brown et al, 1989), preservation of vaginal length and function (Morley and DeLancey, 1988; Brown et al, 1989), and cost-effectiveness (Brown et al, 1989). These reported advantages have not been fully re-evaluated in this era of laparoscopic and robotic prolapse repairs. The structures at risk with this technique include the pudendal or inferior gluteal vessels and the sciatic or pudendal nerves. Pudendal nerve entrapment results in posterior buttock pain, which may radiate down the back of the thigh. A disadvantage of this approach is the alteration in vaginal axis, which results in apical displacement posteriorly and to the right side when unilateral fixation is used. This posterior displacement can result in anterior compartment recurrence even when an anterior repair is performed (Morley and DeLancey, 1988; Shull et al, 1992; Sauer and Klutke, 1995).

Sacrospinous fixation may be performed unilaterally or bilaterally (Pohl and Frattarelli, 1997). With the unilateral suspension, right-sided placement is generally preferred. Technically, it is easier to place the sutures on the right ligament for a right-handed surgeon (Sauer and Klutke, 1995). Cespedes reported success using the bilateral anterior support and noted the advantage of a more midline location of the vaginal apex (Cespedes, 2000). Although bilateral placement has been advocated (Nichols, 1996), there is little to support the advantage of bilateral fixation over unilateral fixation when examining outcomes (Morley and DeLancey, 1988).

Figure 83-27. A, Three permanent sutures are placed in each of the uterosacral ligaments medial to the ischial spine. B, One end of each of the six sutures is placed serially across the vaginal apex through the anterior endopelvic fascia, and the other end is placed through the posterior endopelvic fascia. C, All sutures are tied to reapproximate the anterior and posterior vaginal muscularis, to close any potential enterocele defect, and to elevate the vaginal apex toward the sacrum. Surgical Anatomy of Sacrospinous Ligament Fixation. The SSL is approximately 7 to 8 cm in length (Morley and DeLancey, 1988) and extends from the ischial spine laterally, coursing medially under the coccygeus muscle, and inserts into the sacrum. The pudendal nerves and vessels are in close proximity to the ligament, just proximal to their course around the ischial spine (Fig. 83-28). In addition, the hypogastric plexus of veins is located superiorly and the hemorrhoidal vessels are located medially to the SSL (Morley and DeLancey, 1988); thus retraction should be carried out carefully in these areas. To avoid the gluteal vessels, the suture should be placed into the ligament and not behind it (Kettel et al, 1989). Pudendal nerve entrapment may result in pain, which localizes to the buttocks or perineum. This may be avoided by placing sutures medial to the ischial spine, about 1.5 cm (Sauer and Klutke, 1995; Alevizon and Finan, 1996). Thus the optimal position of the

suture placement is 1.5 to 2.0 cm medial to the ischial spine, directly into the SSL. Placing it too far medially may risk failure of the repair because the SSL fans and thins as it inserts into the sacrum (Sauer and Klutke, 1995). In addition, there is a higher concentration of sacral nerves in this medial location. Barksdale performed a cadaveric study to assess the histology of the SSL, taking segments near the ischial spine and middle and sacral portions of the ligament (Barksdale et al, 1997). The highest concentration of nerves was found in the sacral portion of the SSL, with the lowest being near the spine. Although it was postulated that the nerves embedded in the SSL were a potential source of neuropathic pain, no clinical correlation could be made in this cadaveric study. Lantzsch and colleagues concluded that localization and depth of the suture can also influence the occurrence and intensity of sciatic neuralgia (Lantzsch et al, 2001).

Figure 83-28. Anatomy of the sacrospinous ligament and surrounding structures. Close proximity of the pudendal vessels, hypogastric plexus, inferior gluteal vessels, and sciatic nerve should be noted. (From Walters M, Karram M. *Urogynecology and reconstructive pelvic surgery*. 3rd ed. Philadelphia: Mosby; 2006.)

Technique. The procedure starts by marking the apex of the vagina. The vaginal apex is then reduced to the SSL(s) intended to be used. This site of attachment is then tagged (or marked) for later fixation. Depending on concomitant compartmental defects, the SSL can be approached either anteriorly or posteriorly. A standard midline vaginal incision is made and the vaginal epithelium is separated from the rectovaginal septum posteriorly or the pubocervical fascia anteriorly. If an anterior compartment repair will be performed, the SSL may be approached anteriorly, exposing the paravesical space. The tissue attachments overlying the spine and ligament are swept medially. Alternatively, if the posterior approach is used, one must enter the perirectal space by bluntly mobilizing the rectum medially. On entrance to the perirectal space, the ischial spine is identified. With further dorsal and medial blunt dissection, the SSL is palpated. Blunt dissection is continued to ensure that the rectum is retracted medially, and the ligament is adequately exposed. At this point Heaney or Breisky-Navratil retractors are very useful to visualize the ligament and facilitate suture placement. In addition, lighted retractors can provide added visualization. The SSL is then palpated. The suture is placed approximately one to two fingerbreadths medial from the spine to avoid damage to the structures in the Alcock canal. Several different methods have been used to fix the suture to the sacral spinous ligament. The Capiro Suture Capturing Device or the Capiro "Thin" Suturing Device (Boston Scientific) enables the suture to be placed by palpation. Alternatively, the Miya Hook (CooperSurgical, Trumbull, CT) (Miyazaki, 1987), the Auto-suture Endo Stitch suturing device (Covidien, Norwalk, CT) (Schlesinger, 1997), a Deschamps ligature carrier, or freehand needle driver passage may be used to place the sutures under direct vision. Two sutures are most commonly placed. In cases of bilateral SSLE, one suture may be placed on each ligament. In the case of unilateral SSLE, the placement of the sutures on the ligament 2 cm apart will prevent constriction of the vaginal apex. Additional repairs may be performed at this point. Following this, the previously placed SSL sutures are brought out of the vagina to the previously marked vaginal apex (Fig. 83-29). If a permanent suture is

Figure 83-29. Sacrospinous ligament fixation. With a unilateral suspension, the vagina is deflected to the right side and caudally. (From Richter K, Albright W. Long-term results following fixation of the vagina on the sacrospinous ligament by the vaginal route [vaginaefixatio sacrospinialis vaginalis]. *Am J Obstet Gynecol* 1981;141: 811-6.)

used for SSLE, a pulley-stitch configuration, which ensures that the knot of the suture will remain internal, is needed. To create a pulley stitch, a knot is tied onto the fibromuscular portion on the visceral side of the vagina to create a fixed point. The free end of the suture is then pulled, thus suspending the apex to the SSL; this is then secured by tying a secure knot. Importantly, this resultant knot

remains internal and is not within the vaginal canal. Closure of the vaginal wall halfway before the sutures are tied down is useful, because the suspended apex may be quite difficult to reach. The sutures should be tied such that the vaginal apex is firmly attached to the coccygeal SSL complex with no intervening suture material bridging a gap (Morley and DeLancey, 1988; Sze and Karram, 1997). Palpation of the suture behind the vaginal cuff will ensure that the suture is tied securely. It is useful to leave the secured suture untrimmed until the cystoscopy is performed in case the suture needs to be removed. Once the efflux is visualized bilaterally, the anchoring suture is trimmed, and the remainder of the vaginal incision is closed.

Results (Table 83-6). Nichols reported outcomes of SSLF in 163 patients, some with “massive” vaginal eversion and procidentia. There were no reported recurrences of vaginal vault prolapse; however, 9 patients reported that the vagina was “too narrow” postoperatively (Nichols, 1982). This outcome was also observed in a study by Richter, who reported excellent patient satisfaction, although 8 patients were reluctant to resume sexual relations because of a perception of vaginal narrowing (Richter and Albrich, 1981). Morley and DeLancey reported on 100 patients who underwent SSLF, 33 of whom underwent isolated apical treatment, and 67 had concomitant prolapse repairs (Morley and DeLancey, 1988). Apical success was noted in 95.7%, 90.1% globally, with 4 patients having prolapse in the anterior compartment. The researchers noted that the long-term results were acceptable with minimal adverse effects.

Bilateral SSL suspension was compared with ASC in a prospective randomized study (Benson et al, 1996). Time to failure was shorter in the SSL group compared with the abdominal group (11 months vs. 22 months), with the vaginal group having 12 cystoceles requiring reoperation versus 4 cystoceles in the abdominal group. Sauer and Klutke reported on 24 patients with a mean follow up of 13.8 months (Sauer and Klutke, 1995). Blood loss was minimal and no transfusions were needed, but mild postoperative buttock pain was noted that resolved by 3 months. In 21 of 24 patients there was no recurrence of prolapse at the apex, but 1 patient underwent repeat operation for a significant cystocele. Meschia and colleagues reported on 103 patients who underwent SSLF and found excellent results for the posterior and apical compartments but disappointing results for the anterior compartment, with 16% having grade 2 or greater prolapse (Meschia et al, 1999).

The anterior compartment has been reported as a particularly vulnerable site for developing a defect after sacrospinous vaginal vault suspension. Recurrent cystoceles have been reported in 7.6% to 92% of patients after surgery (Richter and Albrich, 1981; Morley and DeLancey, 1988; Pasley, 1995). This has been attributed to vaginal retroversion (posterior displacement). This is noted not only postoperatively, but intraoperatively, although many who develop anterior defects remain asymptomatic and do not undergo subsequent surgery to correct the anterior compartment defect (Paraiso et al, 1996).

Several authors have demonstrated the feasibility and efficacy of an anterior approach to the SSL vaginal vault suspension (Cespedes, 2000; Winkler et al, 2000). Winkler reported that the anterior compartment recurrence rate after an anterior SSLF and anterior repair was 9%, in contrast to 24% after SSLF with posterior repair (Winkler et al, 2000). Cespedes reported on the bilateral anterior approach and noted no recurrences. Some of the theoretic advantages of the anterior approach include improved ability of the vagina to withstand increased intra-abdominal pressures (Pohl and Frattarelli, 1997) and less likelihood of rectal injury (Sauer and Klutke, 1995). Again, a low incidence of anterior compartment recurrence was noted, at 7% (Cespedes, 2000).

Successful healing in the short term may predict long-term success of the SSL suspension. Shull and colleagues (1992) reported on 81 women undergoing SSL suspension; 72% had previous pelvic surgery. Those who showed absence of any compartment defect at 6-week follow-up had only a 3% likelihood of requiring additional reconstructive surgery within 2 to 5 years.

Complications. Cruikshank reported that 15% of patients experienced gluteal pain after SSLF on the ipsilateral side (Cruikshank et al, 2003). In general, this pain has shown spontaneous resolution within 2 to 3 months when delayed absorbable sutures are used (Maher et al, 2001). Postoperative neuropathic pain can be managed with observation, and patients should be counseled that duration may be as long as 3 months (Sauer and Klutke, 1995). Injection of the nerve with local anesthetic has been used for treatment (Lantzsich et al, 2001). Rectal perforation has also been reported with this procedure; when recognized at the time of surgery and repaired primarily, no sequelae were observed (Richter and Albrich, 1981; Sauer and Klutke, 1995). In addition, injury to the pudendal nerve and internal pudendal vessels may occur with sutures placed too near the ischial spine.

Iliococcygeus Suspension

The iliococcygeus suspension has the advantage of maintaining the vagina in a more normal axis and is useful when the uterosacral ligaments are insufficient for attachment or cannot be identified. With this technique, the vaginal vault is attached to the fascia of the iliococcygeus muscle as the anchoring site in contrast to the uterosacral ligaments or SSLs.

Technique and Results. The iliococcygeus suspension approach is similar to that of uterosacral ligament suspension and SSLF and is usually extraperitoneal. The fascia of the iliococcygeus muscle is identified lateral to the rectum and distal to the ischial spine (Shull et al, 1993). The point of suture fixation is placed 1 cm distal to the ischial spine, near the insertion of the ATFP. This suture is then passed through the condensation of connective tissue at the apex of the vagina anteriorly through the pubocervical fascia and posteriorly through the rectovaginal fascia (Fig. 83-30). Another suture is placed on the contralateral side in a similar manner. It is recommended that bilateral suture fixation be performed to achieve

†POP staging systems, if used, are indicated as grade for Baden-Walker (Baden and Walker, 1972) or stage for POP-Q (Bump et al, 1996).

ASC, abdominal sacrocolpopexy; NR, not reported; POP-Q, Pelvic Organ Prolapse Quantification System; RCT, randomized controlled trial; SSLF, sacrospinous ligament fixation; SSLS, sacrospinous ligament suspension.

Figure 83-30. A and B, Iliococcygeus fascia suspension. (From Walters M, Karram M. Urogynecology and reconstructive pelvic surgery. 3rd ed. Philadelphia: Mosby; 2006.)

optimal results. Once the sutures are tied securely, the vagina will be suspended bilaterally. As in SSLF, the sutures may be placed through an anterior or posterior approach. Special needle drivers and lighted retraction are useful to facilitate suture placement. In cases using permanent suture, a pulley-stitch technique is applied, with the knot tied internally.

Shull reported on bilateral attachment of the vaginal cuff to the iliococcygeus fascia in 42 patients (Shull et al, 1993). Nine patients experienced pelvic support loss postoperatively, 3 in the middle (apical) compartment, 2 in the posterior compartment, and 4 in the anterior compartment. Six patients required additional surgery. Meeks and colleagues reported an anatomic cure rate of 96% in 110 patients (Meeks et al, 1994). Intraoperative complications included rectal and bladder laceration and hemorrhage requiring transfusion. Postoperative complications included vaginal cuff abscess, fever, and transient femoral neuropathy. Maher and colleagues reported a 53% cure rate in 50 patients; 19% of the patients experienced buttock pain (Maher et al, 2001).

Abdominal Sacrocolpopexy

ASC should be considered a treatment option in the following clinical scenarios: failed previous vaginal repair, isolated uterine prolapse and/or enterocele, younger women, women with a highly active lifestyle, women who are sexually active, and women who desire one of the consistently most durable repairs at the expense of a potentially more invasive approach. In these patients, ASC is an excellent choice because it maximizes functional vaginal length without significant distortion of the anatomic vaginal axis. As discussed earlier, other pelvic floor defects and SUI can be addressed at the same time. In addition to open surgery, robotic assisted laparoscopic and pure laparoscopic approaches have been described and are commonly used today (Sundaram et al, 2004; Rozet et al, 2005; Daneshgari et al, 2006; Elliott et al, 2006). The principles of the operation remain the same regardless of the approach.

Technique. The critical elements of the operation include the use of permanent mesh (type I macroporous, monofilament) as graft material, secure fixation of the graft to the sacral promontory and vaginal cuff, and reduction of a concomitant enterocele.

The patients are positioned in the low lithotomy position, providing both transvaginal and transabdominal access. A Pfannenstiel or low midline abdominal incision may be used, or a laparoscopic or robotic-assisted approach. On entry into the peritoneal cavity, it is important to achieve exposure of true pelvis by careful packing of the small intestine and sigmoid colon. This is accomplished by releasing all adhesions in the pelvis and packing the bowel above the level of the sacral promontory and displacing the sigmoid to the left, exposing the sacral promontory and posterior peritoneum. An incision is made in the posterior peritoneum over the sacral promontory, extending inferiorly along the right lateral aspect of the rectum toward the cul-de-sac. Electrocautery is used when dividing the fatty tissue over the promontory to minimize bleeding and improve visualization. Careful dissection in this area is essential to avoid shearing of presacral veins because severe bleeding may occur. The middle sacral vessel traverses over the promontory and should also be avoided. As the fatty tissue is dissected free, the anterior surface of the sacral promontory is visualized, usually by identification of the anterior longitudinal ligament. Two or three interrupted nonabsorbable sutures are placed in the anterior longitudinal ligament, with care taken to avoid perforation of the midline sacral vessels. In general, sutures are placed under the vessels and tied down over the top of the vessels. Alternatively, if vessels overlie the ligament, bipolar energy can be used on the vessels to prevent bleeding before the sutures are placed. These sutures are safely tagged for later placement into the mesh graft (Fig. 83-31). Alternatively, commercially available tacking devices may be used for securing the graft to the sacral promontory, although minimal data exist to confirm comparable efficacy.

After placement of an obturator (end-to-end anastomosis [EEA] sizer or commercially available vaginal paddle) in the vagina, the

Figure 83-31. Abdominal sacrocolpopexy. Note the incision in the peritoneal cuff overlying the vagina, which exposes the vaginal cuff. Two permanent sutures are then placed in the sacral promontory to secure the graft material. (From Winters JC, Cespedes RD, Vanlangendonck R. Abdominal sacral colopexy and abdominal enterocele repair on the management of vaginal vault prolapse. *Urology* 2000; 56[6 Suppl 1]:55-63.)

Figure 83-32. Abdominal sacrocolpopexy. Synthetic graft material is sutured securely to the vaginal cuff using multiple interrupted permanent sutures. The peritoneal cul-de-sac is closed using linearly placed sutures to obliterate this potential space. (From Winters J, Cespedes R, Vanlangendonck R. Abdominal sacrocolpopexy and abdominal enterocele repair in the treatment of vaginal vault prolapse. *Urology* 2000;56[6 Suppl 1]:55-63.)

enterocele sac, if present, is identified and secured with an Allis clamp. If the enterocele is large, a Halban culdoplasty can be performed by placing linear permanent (or delayed absorbable) sutures through the posterior peritoneum and on the outer surface of rectum up to the vaginal cuff (Geomini et al, 2001). Upward retraction of the sizer will assist in exposing the cul-de-sac. Usually four to six sutures are used to complete adequate cul-de-sac closure. This technique of closure (Fig. 83-32) is in contrast to the Moschowitz

procedure, which involves purse-string closure and may predispose to ureteral angulation and obstruction. Alternatively, if an aggressive posterior vaginal dissection to the perineum is to be performed (see later) for placement of an extended piece of posterior mesh with subsequent retroperitonealization of the mesh, the culdoplasty is usually not needed.

The peritoneum over the vaginal cuff is incised, and the peritoneum is dissected off the cuff of the vagina (see Fig. 83-32). There is significant variability in the amount of vaginal dissection reported. Some perform minimal dissection of the peritoneum and bladder attached to the vagina—enough to fix the mesh for 4 to 5 cm on each side—whereas others describe more extensive dissection that involves lifting the posterior bladder wall and trigone off the underlying vagina as well as dissecting all the way to the perineal body. With the advent of robotic techniques, it seems that more extensive dissections are being carried out with longer mesh segments attached to the bladder, although there are no controlled studies to identify the optimal technique of graft placement to the vagina. Several mesh options exist for ASC, including ready-made Y-shaped soft polypropylene mesh and sheets of soft polypropylene mesh that can be cut and fashioned to the surgeon's preference. A polypropylene, macroporous, monofilament, nonabsorbable mesh is recommended. In general, a 2.0-cm-wide by roughly 6.0-cm-long anterior segment of mesh is sutured to the exposed anterior vaginal wall using six to eight permanent sutures (commonly Prolene, Gore-Tex, Ethibond, or Ti-Cron) (Fig. 83-33). Care is taken to identify the border of the bladder to avoid suturing the graft to the bladder and to secure the most lateral portions of the mesh to prevent folding. An obturator in the vagina is useful to facilitate suture placement and secure the mesh to the vagina. The graft is secured to the vagina by folding over the cuff of the vagina and allowing the long end of the graft to exit posteriorly and extend to the sacrum. (Alternatively, a T-shaped configuration of the graft may be created. The short arm of the T is placed on the top of the vagina, and the long arm of the T is secured to the lower end of the vagina.) The posterior peritoneum is dissected off the posterior wall of the

Figure 83-33. Abdominal sacrocolpopexy: intraoperative view. Permanent mesh material sutured to vaginal cuff. End-to-end anastomosis sizer was used to provide exposure of vaginal cuff. (From Scarpero H, Cespedes R, Winters J. Abdominal approach to the repair of vaginal vault prolapse. *Tech Urol* 2001;7:139–45.)

vagina entering the space between the rectum and vagina. This dissection may be extended to the perineum to allow mesh attachment to the perineal body, a procedure termed *colpoperineopexy* (Cundiff et al, 1997). The posterior segment of the mesh is then attached to the posterior vaginal wall with six to eight interrupted nonabsorbable sutures. At this step, the central sutures from the culdoplasty are placed through the long arm of the mesh if desired.

The graft is then secured to the sacral promontory. Care must be taken to avoid excessive tension. Placing the obturator all the way into the vagina but not pushing the vagina upward establishes the proper length for the graft. The graft is placed along the right lateral aspect of the rectum in the space previously developed by extending the opening of the peritoneum from the sacrum. A space of two fingers' width between the graft and the rectum prevents compression of the rectum over the graft (Fig. 83-34). Tensioning in this fashion is not feasible with a robotic or laparoscopic approach. It requires a visual cue of the mesh attachment while extending the vagina cephalad with an EEA sizer to its maximal length without actively stretching it. The promontory sutures are then brought through the mesh and tied down securely. Any excess mesh is trimmed after fixation to the sacrum. Last, the graft is positioned in the retroperitoneal space by closing the posterior peritoneum over the graft, and covering the graft on the vagina with the superior edge of the anterior peritoneum and bladder flap. Stress incontinence procedures (if indicated) are then performed. Indigo carmine is administered to ensure patency of the ureters. The patient is then examined to determine if any ancillary transvaginal prolapse repairs are needed.

ASC maintains a functional vagina and restores maximal vaginal length and support. In a comparative study, vaginal length was longer after ASC compared with sacrospinous fixation (Given et al, 1993). A nonabsorbable monofilament synthetic mesh should be used during ASC. In a study by Culligan and colleagues, patients undergoing ASC were randomized to either absorbable cadaveric fascia lata graft (Tutoplast) or nonabsorbable monofilament polypropylene. The objective failure rate for recurrence at any other vaginal site was 14 of 44 in the fascial group and 4 of 45 in the mesh group (Culligan et al, 2005).

Numerous reports by multiple authors confirm the success of ASC using mesh, and multiple authors have reported success rates greater than 90% (Snyder et al, 1991; Addison and Timmons, 1993; Webb et al, 1998; Menefee et al, 1999). In addition, there are several randomized, prospective trials comparing SSLF with ASC. In a comparative study between ASC versus vaginal repair, Benson and colleagues reported a lower success rate with vaginal repair, and an equivalent hospital stay between the two groups (Benson et al, 1996). Lo and Wang reported on their results of ASC versus SSLF at a duration of 2.1 years—94.2% success in ASC compared with 80% in SSLF (Lo and Wang, 1998). Maher and colleagues reported on a comparative study between ASC and SSLF. At 2 years' follow-up, symptoms and anatomic success were equivalent but asymptomatic failures to the introitus and recurrent cystoceles were less after ASC (Maher et al, 2004). Overall, vaginal (SSLF) procedures have a higher rate of recurrent anterior defects even when performed in the setting of a concomitant anterior repair (colporrhaphy) (Holley et al, 1995). After an isolated abdominal repair of vaginal vault prolapse without addressing concomitant pelvic floor defects, recurrent distal defects such as cystocele and rectocele may occur up to one third of the time. This may predispose to decreased patient satisfaction and the possibility of secondary vaginal repair (Blanchard et al, 2006). Although most remain asymptomatic, secondary repair of these defects may be required (Blanchard et al, 2006). It is important to counsel patients preoperatively about the possibility of distal anterior or posterior defects after ASC, and the need for secondary vaginal repair, which can occur up to 20% of the time (Blanchard et al, 2006). Recent results from the E-CARE trial show that at 7 years after ASC, the recurrence rate of POP progressively increases. The anatomic treatment failure rates ($C > TVL-2$ or $Ba/Bp > +1$) for ASC with and without Burch urethropexy were 0.27 and 0.22, respectively. It is interesting to note that half of these were asymptomatic. The symptomatic failure

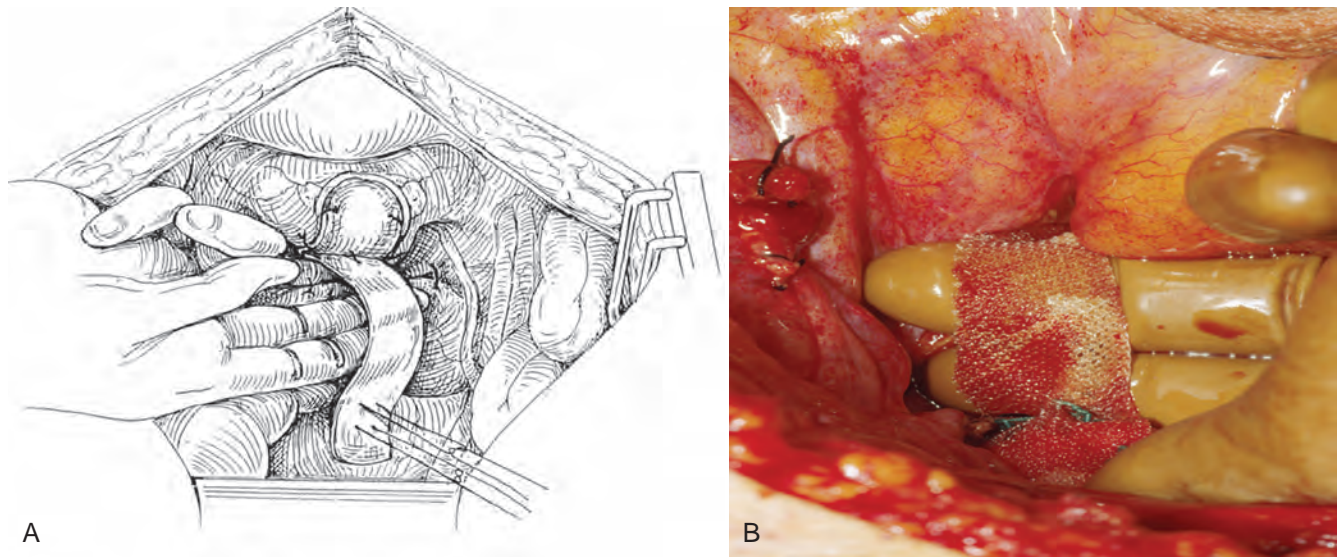

Figure 83-34. Abdominal sacral colpopexy. A, Graft is secured without tension to sacral promontory. B, Intraoperative view. (A, From Winters J, Cespedes R, Vanlangendonck R. Abdominal sacrocolpopexy and abdominal enterocele repair in the treatment of vaginal vault prolapse. *Urology* 2000;56[6 Suppl 1]:55–63; B, from Scarpero H, Cespedes R, Winters J. Abdominal approach to the repair of vaginal vault prolapse. *Tech Urol* 2001;7:139–45.)

(positive response to one or more questionnaire items or re-treatment of POP) rates with and without Burch urethropexy were 29% and 24%, respectively. However, half of these patients were not re-treated. When the researchers looked at the composite failure (met criteria for anatomic or symptomatic failure) rates for ASC with and without Burch urethropexy, they found 0.48 and 0.34 estimated probabilities of treatment failure, respectively (Nygaard et al, 2013).

Laparoscopic sacrocolpopexy has shown equivalent efficacy to open ASC in several retrospective analyses (Paraiso et al, 2005; Hsiao et al, 2007; Klauschie et al, 2009). To date, no randomized trial has compared laparoscopic sacrocolpopexy with ASC. Laparoscopic surgery appears to result in shorter hospital stay, less blood loss, and conflicting data on operative time. The generalizability of this procedure performed in a pure laparoscopic approach has been limited to those with advanced laparoscopic skill sets, because the dissections, suturing, and knot tying have a steep learning curve. Claerhout and colleagues examined the learning curve for this procedure in a laparoscopic approach and found that adequate learning occurred after 60 cases (Claerhout et al, 2009). The advent of robotic-assisted surgery has augmented the adaptation by many surgeons of a minimally invasive approach to ASC. No studies have outlined the learning curve for this approach, but expert opinion would suggest it to be shorter than the laparoscopic approach. Outcome studies are limited, but one retrospective study with short-term follow-up shows similar anatomic outcomes with less blood loss and shorter hospital stay (Geller et al, 2008). Another retrospective review of 95 robotic-assisted sacrocolpopexies with 34-month follow-up had an anatomic success rate of 95.8%. Only one mesh erosion was reported in the postoperative follow-up (Ploumidis et al, 2014). Meta-analysis of seven smaller studies (N = 315) of robotic sacrocolpopexy suggest equivalence to the laparoscopic and open approaches (Maher et al, 2013b). Anatomic success rates ranged from 60% to 100% with a mean of 93%, and subjective success ranged from 91% to 94%. The mean mesh erosion rate in these studies was 5%. In a randomized study of robotic (n = 40) versus laparoscopic (n = 38) sacrocolpopexy, Paraiso and colleagues demonstrated significant improvement in vaginal support and functional outcomes 1 year after surgery, with no differences between groups (Paraiso et al, 2011). Khan and colleagues performed a Medicare database study looking at the

outcomes of open ASC versus laparoscopic (including robotic) sacrocolpopexy. Of the 794 ASC and the 176 laparoscopic cases, apical anatomic success rates were similar, but reoperations for anterior recurrences were higher in the laparoscopic group (3.4% vs. 1.0%, $P = .018$) (Khan et al, 2013).

In a comprehensive review by Nygaard and colleagues, intraoperative complications of sacrocolpopexy included hemorrhage or transfusion (4.4%), cystotomy (3.1%), enterotomy (1.6%), and ureteral injury (1.0%). Postoperative complications included UTI (10.9%), wound infection (4.6%), ileus (3.6%), deep venous thrombosis or pulmonary embolism (3.3%), and small bowel obstruction (1.1%) (Nygaard et al, 2004). Significant hemorrhage may occur from disruption of the presacral vessels, and the occurrence of this complication may be reduced when fixation of the graft is performed higher on the sacral promontory. This bleeding risk has been reported to range from 1.6% to 4.4% and may be controlled with the use of stainless steel thumbtacks in an open ASC (Timmons et al, 1991). Fulgurating these vessels preemptively with bipolar energy, especially during a minimally invasive approach, may preclude this complication. The CARE trial data reveal that the rate of reoperation for gastrointestinal complications with this procedure is 1.2% (Whitehead et al, 2007). Vaginal exposure of mesh is another complication and is heralded by persistent pain, discharge, or infections, and clinicians must be vigilant in follow-up (Karlovsky et al, 2005). In meta-analysis, rates of mesh exposure into the vagina have been reported as 3.4% to 5.4% and may vary with the type of mesh used (Brizzolara and Pillai-Allen, 2003; Nygaard et al, 2004). Exposures occur more often with Teflon or Gore-Tex type materials and are rarer with macroporous, monofilament meshes. Surgeons performing these procedures should be aware of the recently reported 9.9% mesh exposure rate from the extended follow-up of the multicenter CARE trial (Nygaard et al, 2013). Several authors have suggested that hysterectomy at the time of colpopexy increases the rate of mesh extrusion, although these findings are not uniform (Nygaard et al, 2004; Marinkovic, 2008) and no randomized trials have addressed this issue (Nygaard et al, 2004). In 60 patients undergoing concomitant hysterectomy using a two-layer closure of the vaginal cuff followed by ASC with synthetic nonabsorbable monofilament mesh, the exposure rate was 0.8% compared with 0% in the 64 patients with a prior hysterectomy (Wu et al, 2006). In

patients undergoing a combined operation, supracervical hysterectomy or a meticulous two-layer closure of the cuff should be performed to decrease the incidence of mesh exposure. **Surgeons must be aware that the incidence of mesh exposure after ASC is higher after complete hysterectomy. In patients needing hysterectomy, the feasibility of a supracervical hysterectomy should be strongly examined. In this scenario, a supracervical hysterectomy in conjunction with the ASC is preferred. These patients should also be informed that for uterine prolapse, a vaginal hysterectomy with vaginal vault suspension is an effective option as well.** Options for the management of exposed mesh after colpopexy may include TVM excision with or without partial colpocleisis (Quiroz et al, 2008) and abdominal mesh excision.

Colpocleisis

Colpocleisis is an obliterative procedure used in the treatment of posthysterectomy vaginal vault prolapse or significant uterovaginal prolapse. In properly counseled, older patients who do not desire a functional vagina for sexual activity, colpocleisis may be an appropriate, noninvasive procedure. The total colpocleisis is performed in patients who have undergone hysterectomy and refers to removal of the vaginal epithelium to approximately 2 to 3 cm from the urethral meatus with complete closure. A partial colpocleisis is used in cases of uterovaginal prolapse; this procedure involves creating lateral channels to allow potential uterine drainage. Advantages of the colpocleisis procedures are shorter operative time, ability to use regional anesthesia or local anesthesia with sedation, minimal complications, minimal recurrence, and decreased recuperative time (Cespedes et al, 2001; Fitzgerald et al, 2008). In those whose uterus is to be left in situ, preoperative evaluation should include a Papanicolaou smear, pelvic sonogram, and endometrial biopsy if indicated. Performance of hysterectomy at the time of colpocleisis eliminates the risk of developing cervical or endometrial cancer and eliminates the risk of developing pyometra, which is a serious complication of partial colpocleisis when the channels become obstructed (Shayya et al, 2009). However, most patients selected for colpocleisis are older with significant comorbidities that make a concomitant hysterectomy undesirable.

Technique

Partial Colpocleisis. The patient is placed in standard lithotomy position. A Foley catheter is placed into the bladder. If an anti-incontinence procedure is needed, it may be performed first. The cervix is grasped with a tenaculum, and a rectangular segment of vaginal epithelium is marked anteriorly and posteriorly. The excision of the vaginal epithelium will extend 3 cm from the urethral meatus to 3 cm from the cervix (Cespedes et al, 2001). It is important to leave sufficient vaginal epithelium laterally to allow creation of the lateral channels to facilitate drainage. The epithelium is then excised. It is optional to place a 14-Fr red Robinson catheter along the vaginal sidewalls to assist in forming the channels. Then, starting at the leading edge of the prolapse, one places successive layers of 2-0 delayed absorbable sutures, which plicate and reduce the prolapse until the prolapsed tissues are above the levator plate (Fig. 83-35A). The sutures are placed in transverse rows consisting of linear sutures through the pubocervical fascia anteriorly and rectovaginal fascia posteriorly. As these sutures are tied, the apical prolapse is reduced proximally (Fig. 83-35B). Successive rows of sutures are placed until the apical prolapse is completely reduced. A high perineorrhaphy is performed by removing a triangular segment of the vaginal epithelium. The fibromuscular tissues of the perineal body are approximated in the midline with absorbable sutures to narrow the introitus. Figure 83-36 shows the completed procedures. Indigo carmine is administered and a cystoscopy is carried out to confirm ureteral patency.

Total Colpocleisis (Fig. 83-37). Total colpocleisis differs from partial colpocleisis in that the lateral channels are not left in place, but rather, the entire prolapsed vagina is denuded of its epithelium from the apex to 3 cm proximal to the urethral meatus. The dissection is carried laterally and continued to the posterior lateral sulcus. The prolapse sac is dissected away from the vaginal epithelium.

Usually the enterocele reduces easily, and no further treatment is necessary (Cespedes et al, 2001). At this point, the colpocleisis is carried out starting at the leading edge of the prolapse. Purse-string sutures of 2-0 absorbable suture are placed circumferentially around the prolapse including pubocervical and prerectal (rectovaginal) fascia (Fig. 83-37A). As each progressive suture is tied, the prolapse is reduced proximally (Fig. 83-37B). These progressive purse-string sutures are carried out until the prolapse is adequately reduced. Alternatively, the prolapse may be reduced as described for the partial colpocleisis by placing transverse rows of interrupted sutures (see Fig. 83-37C). As these rows are tied, the prolapse is reduced proximally. Successive rows of sutures are placed until the prolapse is fully reduced. The remainder of the procedure is carried out as described for the partial colpocleisis. After the prolapse is reduced, the posterior vaginal wall and perineum are repaired. A high perineorrhaphy (levator myorrhaphy) is important to narrow the introitus and prevent recurrence. Cystoscopy to ensure patency of the ureters is recommended. For both techniques, success depends on the amount of vaginal tissue sutured together. This creates a septum of support, which is enhanced by bringing the levator muscles together along with the perineorrhaphy.

Several authors have reported that it is unnecessary to open the enterocele sac if one is present, because the repair will close the potential space in which the bowel might protrude (DeLancey and Morley, 1997; Glavind and Kempf, 2005). If the enterocele sac cannot be reduced, then purse-string absorbable sutures incorporating the sac and the uterosacral remnants can be used to reduce the sac (Cespedes et al, 2001).

Results

Colpocleisis. DeLancey reported on 33 women who underwent colpocleisis over a 20-year period (DeLancey and Morley, 1997). In this study, opening of the enterocele sac was avoided. One vaginal eversion recurrence was noted. The patient was treated with repeat colpocleisis and had a good response 1 year after the second colpocleisis. All but 1 patient expressly denied regret over the decision to have an operation that precluded the ability to have intercourse; however, 1 "accepted" her sexual inactivity. Many indicated relief of the discomfort associated with the prolapse and were positive about the outcome of the operation. Cespedes reported on 38 patients who underwent a mean of 24 months' follow-up (Cespedes et al, 2001). There was no recurrent prolapse. Three patients who had a Kelly plication for incontinence had mild SUI, and two were treated successfully with collagen. All were satisfied with the procedure, and no complications were noted. Von Pechmann reported on a large study of 92 patients who underwent colpocleisis (von Pechmann et al, 2003). Patients were followed by examination and phone survey, which appraised satisfaction and regret. Regret over the loss of coital ability was expressed in 12.9% or 8 patients. In a multicenter, prospective study designed to study the effect of colpocleisis on pelvic support, symptoms, QoL, morbidity, and postoperative satisfaction, Fitzgerald and colleagues reported on 152 patients with 1-year follow-up (FitzGerald et al, 2006). Eighty-four percent stated they were either very satisfied or satisfied about the decision for vaginal closure. One patient was dissatisfied, and one was very dissatisfied. One patient underwent repeat colpocleisis for recurrence. Most patients did not experience worsening of their body image. Koski and colleagues reported on 53 patients undergoing colpocleisis; 74% had a total colpocleisis; 91% described the procedure as successful on the PGI-I scale, and examinations correlated with these findings. Urinary frequency and urgency were the most bothersome symptoms reported in 33% of patients (Koski et al, 2012).

Partial Colpocleisis. Goldman and colleagues reported on 118 patients who underwent Le Fort colpocleisis (Goldman et al, 1981). Good anatomic results were noted in 107 patients, with 101 reporting a relief of symptoms. There were 3 recurrences but none of the patients underwent further operative therapy. Immediate postoperative complications included one pulmonary embolus, fever, and UTI. Langmade and Oliver reported on 102 patients (Langmade and Oliver, 1986). There were no recurrences and no de novo stress incontinence; 16 patients had transient postoperative urinary

Figure 83-35. A, Partial colpocleisis is started by excising rectangular portions of the vaginal epithelium, leaving lateral channels. The cervix is then everted over a red rubber catheter. B, The cervix is everted as the prolapse is reduced. (A, From Baggish M, Karram M. *Atlas of pelvic anatomy and gynecologic surgery*. 3rd ed. Philadelphia: Saunders; 2010; B, from Cespedes RD, Winters CW. *Colpocleisis for the treatment of severe vaginal vault prolapse*. In: Vasavada SP, Appell RA, Sand PK, et al, editors. *Female urology, urogynecology, and voiding dysfunction*. Boca Raton [FL]: Taylor & Francis; 2005.)

Figure 83-36. The partial colpocleisis is completed along with peri-neorrhaphy. (From Cespedes RD, Winters CW. Colpocleisis for the treatment of severe vaginal vault prolapse. In: Vasavada SP, Appell RA, Sand PK, et al, editors. *Female urology, urogynecology, and voiding dysfunction*. Boca Raton [FL]: Taylor & Francis; 2005.)

retention. There was no reported regret regarding the ability to engage in sexual intercourse. In a retrospective series of over 300 women, the anatomic success rate was 98.1%, with a patient satisfaction rate of 92.9%. These authors concluded that colpocleisis is an effective and low-risk procedure for the appropriate elderly patient with advanced POP (Zebede et al, 2013).

Crisp and colleagues reported on body image, regret, and satisfaction after Le Fort and total colpocleisis. This multicenter trial confirmed the results of earlier studies, which demonstrated improved body image, improved pelvic floor symptoms, low levels of regret, and high levels of satisfaction (Crisp et al, 2013). Urinary incontinence after colpocleisis may occur and has been attributed to several mechanisms. Occult stress incontinence may be unmasked with reduction of the urethrovesical angle as described earlier. An alternative mechanism, secondary to traction on the urethra when it is approximated with the posterior vaginal muscularis, has been proposed (FitzGerald et al, 2006). Thus it is recommended to avoid colpectomy of at least 1.5 cm of the distal anterior vaginal wall adjacent to the urethral meatus (FitzGerald et al, 2006). As with other prolapse cases, the recommendation of a concomitant anti-incontinence procedure in an asymptomatic patient is controversial and remains to be substantiated by prospective studies. However, it is clear that these women may develop SUI postoperatively. Thus all women before undergoing colpocleisis should be screened for the presence of occult SUI, and anti-incontinence procedures should be offered concomitantly in women with symptoms of SUI or occult SUI. In addition, in frail, elderly patients there is concern for urinary retention, frequently the result of impaired contractility (which may be appreciated preoperatively) and other perioperative factors. This may be more difficult to

manage because these patients are more likely to be unable to perform intermittent catheterization. These possibilities must be discussed with patients in advance of surgery. Patients considered at significant risk for retention should be offered a suprapubic tube to assist in bladder management postoperatively.

Uterine Prolapse

POP was the indication for 16.3% of all hysterectomies performed from 1988 to 1990 (Owings and Kozak, 1998). Although the majority of hysterectomies are performed transabdominally, the vaginal approach offers the advantages of less invasive surgery and the ability to repair concomitant pelvic floor defects (Eilber et al, 2004).

The uterus is suspended in the pelvis by the cardinal-uterosacral complex. The body of the uterus is enveloped between the two leaves of the broad ligament, which also surrounds the fallopian tube, round ligament, and ovarian ligament along with the uterine and ovarian vessels. The broad ligament does not provide significant support (Eilber et al, 2004). Therefore the defect prompting uterine prolapse is in the form of attenuated ligaments or specific breaks in the continuity of the cardinal-uterosacral complex. Contraindications for the vaginal approach are endometriosis of unknown extent, obliteration of the cul-de-sac, large fibroids (size disproportion to the introitus), pelvic tumor, adnexal tumor, and malignancy of the uterus or ovaries (Eilber et al, 2005).

Transvaginal Hysterectomy

Technique. The patient is placed in the dorsal lithotomy position. A catheter is placed to drain the bladder. Retraction of the labia with a ring retractor and stays is useful. Two Lahey clamps are placed on the cervix. Care must be taken to place it on the most distal portion of the cervix, as the bladder may descend fairly low on the anterior vaginal wall. The incision is made full thickness through the vaginal epithelium around the cervix approximately 1 cm from the cervical os. The posterior peritoneal fold is exposed by applying traction to the tenaculum and using a right-angle retractor to apply counter-traction to the vagina. Once the posterior peritoneal fold is identified, it is opened sharply to enter the cul-de-sac. Once the cul-de-sac is entered, the uterus and adnexa can be palpated to check for pathology. The anterior dissection is performed on the glistening white surface of the uterus, which confirms the correct plane of dissection. Traction on the cervix with countertraction applied anteriorly will facilitate the dissection of the vesicouterine space. The peritoneum is identified anteriorly and entered. The uterosacral ligament can then be identified for suspension to restore the vaginal cuff once the uterus has been removed.

The cardinal and uterosacral ligaments are isolated, divided, and suture-ligated with delayed absorbable suture. The uterine arteries are identified and ligated. If the ovaries and adnexa are to be left in situ, the utero-ovarian ligament, Fallopian tube, and round ligaments are divided and suture-ligated. The remainder of the broad ligament is divided bilaterally and the uterus removed. It is not unusual to have an elongated cervix with prolapse, which can make visualization of the fundus of the uterus challenging. All pedicles are examined for hemostasis.

Vaginal vault suspension is crucial because the hysterectomy alone will not restore the anatomy of the vaginal vault. This can be accomplished by placing sutures through the apex of the vaginal wall and into the uterosacral or sacrospinous ligaments. These sutures are not tied down until after the culdoplasty is performed and the cuff is closed. Purse-string sutures of 0 Vicryl are placed to close the cul-de-sac. These sutures incorporate the pubocervical fascia, cardinal-uterosacral ligament complex, broad ligaments, and perirectal fascia. Care is taken to avoid ureteral injury, which can occur if sutures are placed too laterally on the pubocervical fascia. The vaginal cuff is closed in a continuous locking or interrupted fashion. The vault suspension sutures are tied, suspending the vaginal vault and restoring vaginal depth. Cystoscopy is then performed to ensure ureteral patency and absence of bladder injury.

Figure 83-37. Total colpocleisis. A, A circumferential incision is created at the base of the prolapse. B, Purse-string sutures are placed in the prolapsed tissues to reduce it. C, The vaginal epithelium is closed transversely. (From DeLancey JO, Morley GW. Total colpocleisis for vaginal eversion. *Am J Obstet Gynecol* 1997;176:1228–35.)

Uterine Preservation

Traditionally, surgical repairs to restore pelvic floor support in the setting of uterine prolapse included hysterectomy. Recently, however, there has been great interest in preservation of the uterus with use of prolapse surgery to maintain future fertility, decrease surgical risk associated with the hysterectomy, and satisfy women who wish to

retain their uterus and who feel concerned about sexual function with the loss of their uterus (Maher et al, 2013b). Uterine preservation is considered safe in select groups of women but is contraindicated in those with abnormal uterine and cervical pathology, abnormal menstrual bleeding, postmenopausal bleeding, familial cancer with *BRAC1* and *BRAC2*, hereditary nonpolyposis colon cancer, tamoxifen therapy, and poor compliance with

routine gynecologic care. Frick and colleagues demonstrated a 13% risk of endometrial cancer or hyperplasia in women with postmenopausal bleeding and prior negative evaluation (Frick et al, 2010).

Vaginal Hysteropexy

Vaginal hysteropexy can be performed with and without the use of mesh. The Manchester procedure may be used for this indication, but its main use currently appears to be for the treatment of cervical elongation. It involves amputation of the cervix with reattachment of the cardinal ligaments. The sacrospinous hysteropexy attaches the cervix or uterosacral ligaments to the SSL. In 2010, Dietz and colleagues randomized 37 women to sacrospinous hysteropexy and 34 to vaginal hysterectomy with uterosacral ligament suspension and demonstrated a 21% risk of apical recurrence in the hysteropexy group versus 3% in the hysterectomy group ($P = .03$) (Dietz et al, 2010). Both groups had a high rate of postoperative anterior wall prolapse (50% hysteropexy, 65% hysterectomy, $P = .2$). No difference in functional outcome or QoL was reported. Hysteropexy was associated with a shorter length of hospital stay, earlier return to work, and longer total vaginal length (8.8 cm vs. 7.3 cm, $P < .01$). Meta-analysis of 428 women who underwent sacrospinous hysteropexy and 262 who underwent transvaginal hysterectomy with a variety of suspension procedures revealed an 87% anatomic success rate in the hysteropexy group versus 93% in the hysterectomy group ($P = .054$) (Maher et al, 2013a). Failures tend to occur in those with severe advanced prolapse; high-risk women should consider concomitant hysterectomy to achieve a durable response.

Vaginal mesh hysteropexy typically involves the use of trocars or a Capio device to facilitate the passage of mesh arms through the SSL. The mesh is positioned on the proximal anterior wall to support the cervix and reinforces the anterior plication for reduction of the cystocele. There are a few retrospective cohort studies reporting efficacy of vaginal mesh hysteropexy. McDermott and colleagues used Total Prolift (Ethicon) with ($n = 65$) and without ($n = 24$) concomitant hysterectomy in a nonrandomized fashion (McDermott et al, 2011). Mean follow-up was 10.8 months; hysterectomy patients were found to have a significantly higher POP-Q point C measurement (7.9 cm vs. 6.8 cm; $P = .05$) and longer genital hiatus (3.8 cm vs. 3.3 cm; $P = .03$) than patients who underwent hysteropexy. The clinical significance of this difference is likely meaningless and may simply represent the presence of the cervix occupying the apical portion of the vagina. There were no significant differences for other POP-Q measurements, mesh erosion rates (8% vs. 13%; $P = .7$), or patient-reported outcome measures. Meta-analysis of 316 cases of mesh hysteropexy reported a success rate of 86%, with a mesh exposure rate of 8.8%. A large multicenter trial is underway comparing vaginal mesh hysteropexy using Uphold LITE (Boston Scientific) versus vaginal hysterectomy with uterosacral ligament suspension (NICHD Pelvic Floor Disorders Network, 2014).

Abdominal Hysteropexy

Early reports of abdominal hysteropexy described suturing of the uterus directly to the sacral promontory (anterior longitudinal ligament) or attaching a strip of autologous fascia between the cervix and the promontory. Additional techniques have used a variety of grafts to harness support, commonly the use of polypropylene mesh secured posteriorly to the cervix and posterior vaginal wall with an anterior segment that is passed through the broad ligament to support the anterior cervix and anterior vaginal wall. Meta-analysis of the available data suggests a 63% to 100% (mean 91%) anatomic success rate and a 1.5% mesh exposure rate (Maher et al, 2013b).

Uterosacral hysteropexy is performed by plicating the uterosacral ligaments and anchoring the cervix with or without the addition of a culdoplasty. Minimal high-quality data exist comparing this technique with the others mentioned earlier or with hysterectomy. Meta-analysis of 176 laparoscopic uterosacral hysteropexy reports an 83% success rate (Wei et al, 2012).

KEY POINTS: APICAL COMPARTMENT REPAIR

- The apical compartment is the cornerstone of vaginal support. Failure to ensure apical support at the time of prolapse correction will undoubtedly increase the risk of recurrence.
- Suture placement into the intermediate segment of the uterosacral ligament provides a stable fixation point and decreases the chance of ureteral injury.
- SSLF may result in posterior displacement of the vaginal apex and increase the risk of anterior compartment prolapse.
- Abdominal sacral colpopexy should be performed with permanent graft material and is an excellent option for correction of middle compartment defects. Minimally invasive techniques using laparoscopy and robotic-assisted surgery show similar efficacy.
- Women with uterine prolapse who undergo hysterectomy should have a concomitant vaginal vault suspension to prevent recurrent prolapse.
- Hysteropexy may offer women with less severe prolapse a uterine-sparing option.

Posterior Compartment Repair

Symptoms attributable to posterior compartment prolapse can be divided conceptually as herniation symptoms, defecatory dysfunction, and sexual dysfunction (Cundiff et al, 2004). Herniation symptoms include vaginal bulging and bleeding of the epithelium from excoriation. Defecatory dysfunction includes stool trapping requiring vaginal splinting or manual digitations, defecatory urgency, and constipation. It is important to differentiate among outlet obstruction (including defects in the support of the posterior compartment, perineum, and rectum), motility disorders, and anismus (Cundiff et al, 2004). Anismus is the failure of the puborectalis to relax during defecation. Motility disorders, which usually involve impaired transit of the rectum and anus, are treated with dietary modifications and medication. Anismus responds to biofeedback, and pelvic floor support defects are treated surgically. In combined disorders, it is recommended that nonsurgical treatment for anismus or slow-transit constipation (the most common disorder of motility) be treated before embarking on surgical intervention. Sexual dysfunction is thought to be secondary to dyspareunia, although decreased desire and anorgasmia may also be contributing factors (Handa et al, 2004). Several authors have sought to identify patient factors that would predict who might benefit most from rectocele repair (Murthy et al, 1996; Watson, 1996). These include sensation of vaginal mass or bulge, need for digitalization (splinting) to complete rectal evacuation, nonemptying or partial emptying on defecography, and presence of a large rectocele. Sensation of incomplete emptying and constipation are not specific to rectoceles and may be associated with other disorders including irritable rectum and slow-transit constipation. **Patients should be counseled that surgical repair of the posterior compartment may likely reduce vaginal protrusion symptoms and decrease or eliminate the need for vaginal splinting. However, some patients may have persistence of constipation, because motility disorders and anismus can independently coexist with prolapse and persist after a seemingly successful repair.**

Rectoceles can be approached transanally or transvaginally. Nieminen and colleagues randomized 30 patients to rectovaginal fascia plication or transanal repair (Nieminen et al, 2004). Both approaches resulted in a high rate of symptom resolution (93% for the vaginal approach vs. 73% for the transanal approach.) However, the vaginal approach had better objective findings and a lower rate of prolapse recurrence (7% vs. 66%). The traditional posterior colporrhaphy was devised in the 19th century to treat perineal tears,

which occurred during vaginal delivery. The original description involved plicating the pubococcygeus muscles and the posterior vaginal wall and reconstruction of the perineal body, which was termed *posterior colpoperineorrhaphy* (Cundiff et al, 2004). This resulted in a rigid inferior shelf, which reduced the herniation of the posterior wall and prevented descensus of the vaginal vault or uterus. In 1961, Francis and Jeffcoate reported a high incidence of dyspareunia after colporrhaphy with levator plication (Francis et al, 1961). In their series of 243 women, 50% developed postoperative dyspareunia. In addition, there is evidence to suggest that the traditional posterior colporrhaphy with levator plication may worsen defecatory symptoms. Khan and Stanton reported increased symptoms of fecal incontinence, constipation, incomplete evacuation, and dyspareunia postoperatively (Khan and Stanton, 1997). Because of the increase in dyspareunia postoperatively, plication of the levator ani muscles has largely been abandoned. Site-specific repairs and midline fascial plication without levator ani plication have emerged as the predominant surgical treatments of rectocele. It is important to remember that level 1 and 2 evidence supports the superior objective outcomes of midline posterior plication without levatorplasty compared with site-specific repairs.

Posterior Colporrhaphy

Technique (Fig. 83-38). The patient is placed into dorsal lithotomy position. If a patient requires an anterior or middle compartment repair, it is performed first (Rovner and Ginsberg, 2001). The anterior wall can be retracted with a Heaney retractor to improve visualization. Hydrodissection may be accomplished by injecting saline or a local anesthetic. A midline incision is made on the posterior vaginal epithelium. For a high rectocele the incision may be as high as the vaginal apex; for smaller rectoceles the incision is started at the most caudal position. The rectovaginal fascia (muscularis) is separated from the vaginal epithelium with Metzenbaum scissors. The tips of the scissors should be pointed toward the vaginal epithelium to avoid rectal injury. The dissection proceeds laterally until the pararectal attachments to the pelvic sidewall are visualized. In cases of large posterior defects, a purse-string suture of 2-0 or 3-0 absorbable suture may be placed at the base of the rectal herniation to reduce it; however, care should be taken to avoid foreshortening the posterior wall cephalad to caudad. In addition, this acts to bring the attenuated rectovaginal tissue together to aid in its reapproximation. The rectovaginal tissue is then plicated in the midline with either interrupted or continuous 2-0 absorbable suture. Care is taken to avoid excessively lateral placement or wide spacing of these sutures, which could result in painful ridges along the posterior vaginal wall. Suture placement is continued distally and incorporated into a perineal body reapproximation. The excess vaginal epithelium is trimmed and closed with an absorbable 2-0 suture. A perineorrhaphy may also be performed before the vaginal epithelium is closed.

Site-Specific Repair. To minimize complications associated with posterior colporrhaphy, a site-specific defect repair was described. Richardson described discrete defects in the rectovaginal fascia found in both patients undergoing posterior colporrhaphy and cadaveric dissections (Richardson, 1993). He found that the most common defect was the transverse configuration, separating the vaginal septum from the perineal body (Fig. 83-39). This essentially results in a separation of the rectovaginal tissues from the perineal body. The goal of the site-specific repair is to restore the anatomy by closing these discrete defects.

A midline incision is made on the posterior vaginal epithelium. For a high rectocele the incision may be as high as the vaginal apex; for smaller rectoceles the incision is started at the most caudal position. The rectovaginal fascia (muscularis) is separated through a virtually bloodless plane from the vaginal epithelium. The index finger of the nondominant hand is then inserted into the rectum to facilitate identification of the fascial defect. The defect is closed with absorbable interrupted sutures. The excess vaginal epithelium is trimmed and the vaginal epithelium is closed with interrupted sutures.

Figure 83-38. A and B, Technique of posterior colporrhaphy with rectovaginal tissue plication. (From Ginsberg D. Treatment of vaginal wall prolapse. In: Goldman H, Vasabada S, editors. Female urology: a practical clinical guide. Totowa [NJ]: Humana Press; 2007. p. 281–96.)

Figure 83-39. A and B, Site-specific rectocele repair. A low transverse defect is identified and repaired primarily. (From Richardson AC. The rectovaginal septum revisited: its relationship to rectocele and its importance in rectocele repair. *Clin Obstet Gynecol* 1993;36:976–83.)

Perineorrhaphy. A triangular incision at the mucocutaneous junction is made (Rovner and Ginsberg, 2001). The triangular island of posterior vaginal wall is sharply removed from the prerectal levator fascia. Horizontal mattress sutures are used to approximate the attenuated perineal body fibromuscular tissue. Once these are brought together, the muscles of the urogenital diaphragm are reconstituted and support is restored to the central tendon. It is important that a smooth contour be created along the suture line, because ridges may cause dyspareunia. A vaginal packing moistened with saline, antibiotic solution, cream, or gel is then placed.

Results (Table 83-7). Kahn and Lopez reported on the anatomic and functional results of posterior repair using levator plication. Both reported anatomic success; however, many patients complained of bowel symptoms and dyspareunia postoperatively (Khan and Stanton, 1997). Because of these adverse events associated with levator plication, this technique has been largely abandoned.

Paraiso and colleagues randomized patients prospectively to posterior colporrhaphy (rectovaginal fascial plication), site-specific repair, or site-specific repair with porcine SIS graft (Paraiso et al, 2006). They found that posterior colporrhaphy and site-specific rectocele repair had similar functional and anatomic outcomes. The addition of the porcine-derived graft did not improve anatomic outcomes. Rates of dyspareunia did not differ when comparing all three groups. In a follow-up study of these same patients specifically looking at bowel symptoms, Gustilo-Ashby found that anatomic cure was associated with a reduced risk of postoperative straining and sensation of incomplete bowel evacuation, but not with other bowel symptoms (Gustilo-Ashby et al, 2007). They found that bowel symptoms, including feeling of incomplete emptying, straining to defecate, splinting to defecate, and fecal incontinence, improved significantly after rectocele repair. Abramov and colleagues retrospectively studied patients with advanced posterior vaginal prolapse and compared patients who underwent posterior repair with those who underwent site-specific repair (Abramov et al, 2005). They found that the recurrence of posterior defects was higher in the site-specific group compared with the midline plication of the rectovaginal fascia: 33% versus 14% for second degree,

and 11% versus 4% for third degree. In addition, recurrence of symptomatic rectocele was greater in the site-specific group (11% vs. 4%). Rates of de novo dyspareunia and postoperative bowel symptoms were the same in both groups. Maher and colleagues prospectively studied the efficacy of posterior repair with plication of the rectovaginal fascia (Maher et al, 2004). They found that improved anatomic outcome correlated with improved functional outcomes. Eighty-seven percent no longer experienced obstructive defecation postoperatively. Significant improvements were seen in awareness of prolapse, obstructive defecation, straining to defecate, hard stools, dyspareunia, and digitations. Dyspareunia decreased from 37% to 5%. Singh and colleagues reported on a prospective study of 42 women evaluated for bowel, sexual, urinary, and prolapse symptoms as well as anatomic outcomes after fascial plication technique (Singh et al, 2003). At 6-week follow-up, 87% noted the relief of vaginal symptoms to be 73% to 92%. Sixty-five percent had improvement of the defecatory symptoms, and 38% had improvement of sexual discomfort. None of the patients reported de novo dyspareunia or bowel symptoms.

In contrast to the generalized repair of midline plication of the rectovaginal fascia, several authors have reported their experience with site-specific repair. Glavind and Madsen prospectively studied 67 patients who underwent a discrete repair (Glavind and Madsen, 2000). Of the 67 patients, 64 were found to have a discrete defect, which was repaired, and in 3 there was an attenuation of the tissue. At 3-month follow-up, 85% of those who reported bowel symptoms preoperatively reported resolution of symptoms. Two patients (3%) had de novo dyspareunia. Porter and colleagues examined anatomic, functional, and QoL aspects of posterior colporrhaphy in a retrospective study (Porter et al, 1999). Improvement or cure was noted for pain or pressure, vaginal mass, splinting, and difficulty with defecation. Constipation did not significantly change. Preoperative dyspareunia improved in 73% of patients, worsened in 19%, and occurred de novo in 3 patients. Emotional health also improved, specifically thoughts of embarrassment and frustration. Kenton and colleagues reported on 66 patients who underwent

site-specific repair; all patients had reattachment of the rectovaginal septum to the perineal body. Statistically significant symptom relief was noted in the realms of protrusion, manual evacuation, difficult defecation, and dyspareunia. Constipation was unchanged. Three patients developed de novo dyspareunia, and 1 had de novo constipation. At 1 year, 7 of 11 patients who had used manual evacuation preoperatively returned to doing so. The authors commented that this might have been the result of a functional decompensation of the rectum, which is not corrected surgically. Finally, Cundiff reported on the anatomic and functional aspects of discrete fascial defect repair of the posterior compartment (Cundiff et al, 1998). At 12-month follow-up, 86% were noted to have stage 1 or less. Splinting was eliminated in 63% of patients who reported this symptom preoperatively. The mean satisfaction score was 8.6 (10 highest). **The mean improvement did not correlate to the anatomic correction but did correlate with alleviation of defecatory symptoms, stressing the importance of symptom relief being of priority to the patient over anatomic correction.**

Interposition Graft Repairs of the Posterior Compartment

Both synthetic mesh and biologic grafts have been used in posterior repairs, though data are lacking regarding routine use. Also, several authors caution against the use of synthetic materials in the posterior compartment owing to the potential for dyspareunia and visceral erosion, favoring the use of biologic grafts (Chen et al, 2007). Kohli and Miklos reported anatomic outcomes in 43 patients who underwent a site-specific repair with cadaveric dermis; 30 were available for evaluation at an average of 12.9 months. The graft was fixed proximally to the vaginal apex, laterally to the levator ani muscles, and distally to the perineal body. They reported a 93% success rate using the POP-Q grading system (Kohli and Miklos, 2003). Kobashi and colleagues reported using cadaveric fascia lata in 73 patients. With a mean follow-up of 13.7 months, there was an 83% to 89% improvement in symptoms. Ninety percent of those examined had a grade 0 rectocele by the Baden-Walker classification (Kobashi et al, 2005). Dell and O'Kelley used Pelvisoft, a fenestrated, porcine dermal acellular matrix, and reported no wound complications (Dell and O'Kelley, 2005). Contrary to these encouraging results, Altman reported on 29 patients using collagen mesh for symptomatic rectocele (Altman et al, 2005). Twenty-three were available at 3-year follow-up; 41% had recurrence of stage 2 or greater, and 12 of 23 patients reported incomplete rectal evacuation. The researchers advocated further study before recommending the routine use of graft-augmented tissue repair.

A number of authors have used permanent mesh materials via a posterior approach. Using permanent materials, multicompartmental repairs are more commonly performed extending from the SSL to the perineal body. De Tayrac reported on 26 patients with 2-year follow-up (de Tayrac et al, 2006b). Objective and subjective cure rates of 92.3% and 88%, respectively, were observed. Dwyer used a technique whereby Atrium mesh was attached to the SSL bilaterally and to the perineal body (Dwyer and O'Reilly, 2004). Fifty patients underwent posterior repair, 17 of whom had both anterior and posterior repair. No rectocele recurrence was seen at 13 months. Lim and colleagues reported using a composite Vicryl-Prolene mesh (Vypro II, Ethicon) for correction of isolated rectoceles. In this descriptive study, 90 patients underwent loose placement of an interposition graft in the posterior compartment with no primary repair. Success was noted in 27 of 31 (87%) at minimum 6-month follow-up. Five patients with recurrence of the rectocele did not have prolapse in other compartments (Lim et al, 2005). Mercer-Jones and colleagues reported 22 patients who underwent transperineal placement of either Vypro II or Prolene mesh; 77% reported moderate, good, or excellent results after mesh repair (Mercer-Jones et al, 2004).

When deciding on treatment options for the posterior compartment, both the surgeon and the patient should be aware that graft extrusion rates of 1.3% to 12% have been reported (Kobashi et al, 2005; Lim et al, 2005; de Tayrac et al, 2006b, 2007), as well as dyspareunia rates as high as 60% (Milani et al, 2005).

KEY POINTS: POSTERIOR COMPARTMENT REPAIR

- Because motility disorders often coexist with posterior compartment prolapse, patients should be counseled that constipation may persist despite successful anatomic correction.
- Levator ani muscle plication should not be performed during rectocele repair because of the high risk of dyspareunia postoperatively.
- Despite the high cure rates seen with the use of mesh in the posterior compartment, dyspareunia and vaginal extrusion may be significant.
- Repair of the perineal body is often performed at the time of rectocele repair to recreate approximation of the rectovaginal connective tissues to the central tendon of the perineum.

Vaginal Kits

Synthetic TVM kits have been introduced to provide a graft-augmented durable repair. The proposed advantages of kits are a "less invasive" procedure, standardization of technique, standardization of mesh, and the ability to repair multiple compartments through a vaginal approach. The presence of the mesh at the level of the vaginal apex with fixation is in contrast to the traditional colporrhaphy and may provide correction to multiple compartments, thus making comparisons with traditional prolapse repairs challenging. Currently there are a number of vaginal prolapse repair kits on the market. Because of concerns regarding the use of TVM in the treatment of POP, some companies have voluntarily withdrawn their kit products from the market; Prolift (Ethicon), Proxima (Ethicon), and Avaulta (C.R. Bard) are among the most notable. Implanting surgeons must realize that these procedures are using a significantly higher volume of mesh than conventional mid-urethral slings, and some procedures involve placing trocars into the deep pelvic musculature. **Thus, pelvic surgeons must make an informed decision with the patient, which weighs the apparent advantage in anatomic efficacy, decreased invasiveness, and potential durability against the potential morbidity associated with mesh erosion and the possibility of more significant complications unique to these procedures.**

Technique

Trocar-Based Anterior Compartment Repairs. The anterior prolapse repair follows many of the same basic steps for all of the kit procedures. A midline incision is created in the anterior vaginal wall. Hydrodissection may facilitate a deep, full-thickness vaginal dissection. The full-thickness dissection is important to minimize the occurrence of vaginal exposure of mesh. The dissection progresses laterally to the level of the endopelvic fascia, which is entered by sharp or blunt dissection. The pelvic sidewalls are developed until the ischial spines and ATFP are palpated. Stab incisions are made overlying the obturator foramen. The distal incisions are placed in the anteromedial edge of the obturator foramen at the level of the clitoris, and the proximal incisions are placed 2 cm below and 1 cm lateral to the distal incision. The trocars are used to position the arms of the mesh patch along the ATFP. The distal trocars are placed approximately 2 cm from the distal aspect of the pubic bone, and the proximal trocars are advanced along the ATFP, exiting 1 cm distal to the ischial spine. It should be noted that the proximal trocars in the Perigee system are different from the distal needles, which facilitates a deep passage of the proximal devices to the ischial spine. The mesh arms are used to position the mesh appropriately without tension. Sutures are used to fix the mesh both proximally at the level of the vaginal cuff (preferably delayed absorbable or permanent sutures) and distally proximal to the bladder neck with absorbable sutures. Before mesh placement, anterior colporrhaphy may be performed to correct a central defect if present. Cystoscopy is performed to confirm lower urinary tract

Figure 83-40. Transvaginal kits: Elevate transvaginal mesh. (Courtesy American Medical Systems.)

integrity. Care is taken to confirm the absence of excessive tension on each of the mesh arms (or points of attachment) (Fig. 83-40). The vagina is then closed without trimming the vaginal wall to minimize the occurrence of vaginal mesh extrusion. A loosely interrupted vertical mattress closure may be used to create a virtual two-layer closure of the vaginal epithelium.

Apical and Posterior Trocar-Based Repairs. The posterior and apical approach to kit placement does vary among kit devices. The Prolift device used proximal attachment through the SSL, while the Apogee device is fixed proximally 1 cm distal to the ischial spine. For all procedures, the dissection begins with a posterior vaginal incision, which is full thickness. The dissection proceeds laterally and proximally to expose the ischial spine (Apogee). Two stab incisions are made 3 cm lateral and below the anus. With a hand in the vagina retracting the rectum, the trocars are advanced through the ischiorectal fossa. The Apogee trocars exit 1 cm distal to the ischial spine. The mesh is trimmed so that it does not extend to within 1 cm of the perineal body. This avoids mesh complications in the perineum. The mesh is fixed laterally with absorbable sutures. The mesh is fixed with permanent or delayed absorbable suture proximally to the vaginal apex or posterior lip of the cervix. As with the anterior compartment, no trimming of the epithelium is recommended, and closure is completed with absorbable suture.

Non-Trocar-Based Repairs. There are new kits that do not use trocars for mesh placement. After dissection and exposure similar to the trocar-based procedures, the Uphold device (Boston Scientific) uses a Cadio needle driver system to pass the arms of the mesh through the SSL proximally and the ATRP and obturator internus fascia distally to provide anterior support. It may also be deployed posteriorly using the Cadio device as well. The Elevate (American Medical Systems) has a unique “tacking” device, which anchors the graft in the SSL as well as ATRP. The surgical approach and dissection required are similar to those of the aforementioned procedure; however, a tacking device uses fixation to the SSL proximally and the ATRP and obturator internus fascia distally. There is a special tool that facilitates adjustment of mesh tension after the tacking mechanism has been deployed proximally. An advantage of these devices is that there are no trocar passes required through the deep pelvic musculature.

Results. As with all prolapse procedures, there is a paucity of peer-review data to guide the most appropriate usage of transvaginal kits. Much of the literature regarding kits is from the experience with the

Prolift device, not currently available in the United States. Gauruder-Burmester and colleagues reported on a retrospective analysis of 121 women undergoing procedures with Apogee or Perigee mesh. Success rates of 93% were achieved (Gauruder-Burmester et al, 2007). Seventy-seven women were followed prospectively after placement of Perigee mesh for anterior POP. With an 18-month mean follow-up, an objective cure rate of 93% was achieved. Two women had recurrent prolapse symptoms, and 1 required subsequent surgery. Five mesh exposures occurred, and there were no other significant complications (Moore and Miklos, 2009). Rane and colleagues reported on a 5-year prospective experience with the Perigee system for anterior repair. The primary outcome was POP-Q stage 1 or less anterior vaginal wall prolapse, and secondary evaluation included questionnaire and review of clinical database. In 350 patients followed for a minimum of 2 years, a 94.3% anatomic success rate was achieved. Twenty patients (5.7%) had either recurrent prolapse symptoms or stage 2 prolapse. Five required repeat prolapse surgery, 2 having hysterectomy for stage 3 uterine prolapse. Thirty-nine (11.1%) of women had mesh exposure, of whom 34 required mesh excision under anesthesia. Four patients had 16 surgeries for recurrent mesh exposure. Two patients had hematoma—one requiring evacuation and another a transfusion (Rane et al, 2012). In women with SUI and anterior compartment prolapse, the Perigee system was compared with anterior repair in women who underwent a concomitant TVT-O (Ethicon) procedure. With a minimum of 1-year follow-up in all patients, the authors concluded that the anatomic outcomes were significantly better after the Perigee procedure for the anterior defect. Similar cure rates of SUI were seen, although there appeared to be less frequency in the Perigee group. The mesh erosion rate overall was 4.5%, with 2% attributed to the Perigee mesh. The incidence of dyspareunia was similar between groups (Lau et al, 2011). A prospective multicenter trial evaluated Elevate anterior and apical compartment repair. Of the 128 patients, 112 completed 12-month follow-up. The anatomic success rate was 87.7% for the anterior compartment and 95.9% for the apical compartment. The incidence of mesh exposure was 6.3%. A small percentage of patients experienced transient buttock pain (3.9%), de novo stress incontinence (3.9%), retention (3.9%), dyspareunia (3.2%), and hematoma (2.3%). Three of the mesh excision patients required in-office revision, and 3 required revision under anesthesia (Stanford et al, 2013). Rapp and colleagues evaluated the Elevate procedure prospectively in 40 patients for a minimum of 2 years (mean 34 months). These authors also noted that 36 patients experienced anatomic success, with only 4 having recurrent prolapse, of whom 2 were symptomatic. Two patients had mesh exposure, and 1 had transient leg pain. There were significant improvements in the QoL questionnaire assessments, leading these authors to conclude that the Elevate is a safe and effective system for prolapse correction (Rapp et al, 2014). Feiner and colleagues performed a meta-analysis of the peer-reviewed literature and select peer-reviewed gynecologic abstracts to evaluate outcomes and complications following transvaginal synthetic apical suspension procedures. After the Apogee procedure, 525 women had a mean follow-up of 26 weeks (range 10 to 56 weeks). Mean objective success was 95% (range 81% to 100%). In the same meta-analysis, posterior or total Prolift was performed in 1295 women with mean follow-up time of 30 weeks (range 12 to 52 weeks), and the mean objective success rate was 87% (range 75% to 94%) (Feiner et al, 2009). Although these early data demonstrate successful outcomes, it is important to note that serious complications, some unique to these procedures, are being reported. These concerns have prompted comments regarding new procedures and materials for the treatment of incontinence and prolapse, warning that there are insufficient data supporting the routine use of these devices (Ostergard, 2007). In a Cochrane review of POP surgery, Maher and colleagues concluded that “the advantages of a permanent polypropylene mesh must be weighed against disadvantages including longer operating time, greater blood loss, prolapse in other areas of the vagina, new-onset urinary stress incontinence, and the mesh becoming exposed in the vagina in 11% of women. In general, there is a lack of evidence to support TVM operations used in apical or posterior

compartment surgery” (Maher et al, 2013b). In light of this, it is incumbent on physicians to openly discuss these issues with patients. (See overview of mesh controversy, later.)

Complications. Mesh complications are most commonly in the form of mesh exposure or “extrusion.” Extrusion rates of approximately 10% can be expected (Gauruder-Burmester et al, 2007; Feiner et al, 2009). The exposures seem to occur more frequently on the anterior wall, and a concomitant hysterectomy significantly increases the risk (de Tayrac et al, 2007; Gauruder-Burmester et al, 2007). Measures to minimize the occurrence of vaginal mesh exposure are minimizing excessive vaginal wall trimming and closing without tension. Some advocate closing with a vertical mattress technique to separate the graft from the wound (de Tayrac et al, 2006a). Symptoms of mesh extrusion include vaginal discharge, persistent bleeding, pain, dyspareunia, partner pain, dysuria, and recurrent UTIs. Examination by palpation as well as visualization is important to detect this complication. Although some patients can be managed with either observation or local treatment, most will require excision with primary vaginal closure (de Tayrac et al, 2006a). Infected vaginal mesh can lead to sinus formation, abscess, and enterovaginal fistula formation. One case of necrotizing fasciitis with *Staphylococcus aureus* requiring extensive perineal debridement and colostomy has been reported after a kit procedure (Abdel-Fattah et al, 2008).

Unfortunately, significant lower urinary tract erosion into the bladder or urethra has also been reported, with significant consequences (Yamada et al, 2006). Including transvaginal kits systems, the incidences of visceral (including urethra) injuries have been reported from 2.7% to 4.4% (Altman and Falconer, 2007; de Tayrac et al, 2007). The rates of bladder perforation vary from 0.9% to 2.8% (Altman and Falconer, 2007; de Tayrac et al, 2007; Fatton et al, 2007). Bladder perforation after retropubic mid-urethral sling procedures is not uncommon and appears to be a benign event in the presence of adequate bladder drainage (Kuuva and Nilsson, 2002). The fate of bladder injury at the time of mesh prolapse repairs is much less certain. **If the bladder is injured, it is our opinion that the procedure should be completed without a mesh interposition of the anterior compartment, as placing mesh in the setting of a bladder laceration would prohibitively increase the risk of erosion.** Extensive erosions into the bladder necessitating partial cystectomy have been reported (Abdel-Fattah et al, 2008). With urethral injury, the defect should be repaired primarily, and again, mesh or graft placement should not be performed.

Rectal perforation is reported in 0.7% to 2.8% of cases (Altman and Falconer, 2007; de Tayrac et al, 2007). If rectal injury is recognized intraoperatively, synthetic mesh should not be placed (Mercer-Jones et al, 2004; de Tayrac et al, 2006b). Rectal erosion of synthetic mesh may necessitate both rectal and vaginal excision (Hurtado et al, 2007). From these outcomes, it is clear that **if the rectum is perforated, a multilayer closure should be performed; povidone-iodine distention of the rectum should follow to ensure the integrity of the repair, and the procedure should be abandoned.**

The trocars are passed through the pelvic muscular complex for both anterior and posterior kit repairs. The trocars pass near the ischial spine, and significant intraoperative bleeding may occur. This would usually emanate from the pudendal neurovascular bundle, and embolization of the source of bleeding has been reported (Mokrzycki and Hampton, 2007). Multiple authors have reported pelvic hematomas following transvaginal kit procedures (Ignjatovic and Stosic, 2007; LaSala and Schimpf, 2007; Abdel-Fattah et al, 2008). Abdel-Fattah described concerning vascular complications after Prolift and Apogee or Perigee procedures, including arterial injury. Hematomas have also been reported with these procedures (Ignjatovic et al, 2007). Commonly, patients will report unusually more pelvic pain than typically encountered. Computed tomography (CT) is an excellent method to detect hematomas. Thus, if excessive postoperative pain occurs after the procedure, one should consider an evaluation with CT to look for a hematoma. If present, observation with serial hematocrit levels is the appropriate initial evaluation; however, surgical drainage may

be required for expanding hematomas, decreasing hematocrits, refractory pain, or infection.

Local complications such as pelvic pain, defecatory pain, and dyspareunia have been reported after kit procedures (Altman and Falconer, 2007; de Tayrac et al, 2007). When examining these patients, one must carefully look for areas of impaired healing, banding or tenting of the mesh, “trigger points” that elicit pain, and signs of focal inflammation. If these abnormal areas are identified, release of the arms or the site of mesh tension may alleviate these areas of discomfort. When performing the mesh release, one should excise as much offending mesh material as possible before vaginal closure. In cases of infection, granulomas, or persistent draining sinuses, all mesh involved in the infected areas must be removed. If no local incriminating factors are found, a period of conservative therapy consisting of physical therapy, trigger point injections, and other adjunctive techniques should be attempted first.

KEY POINTS: TRANSVAGINAL KITS

- When considering a transvaginal kit for POP repair, one must weigh the increased anatomic efficacy and decreased invasiveness against the potential morbidity of mesh erosion, mesh extrusion, and visceral organ injury.
- To minimize vaginal mesh extrusion, the trimming of the vaginal wall should be minimized and the incision should be closed without tension.
- If either the bladder or rectum is injured during POP repair, mesh interposition should not proceed because the risk of erosion is high in these situations.
- Prompted by over 1000 reports of mesh complications, the FDA in October 2008 issued a warning to both surgeons and patients regarding the transvaginal use of mesh.

The Use of Mesh in Vaginal Surgery: The Current Controversy

The high failure rates of POP and SUI surgery have long been recognized (Olsen et al, 1997). Owing to inherent connective tissue defects that contribute to SUI and POP, surgeons have long sought materials that could augment repairs and result in more durable outcomes. Biologic materials have been used, but unfortunately have had inconsistent results owing to variability of graft function. When mesh is used as a graft in prolapse surgery, there are differences in volume of mesh, sites of mesh implantation, amounts of vaginal dissection, and surgical expertise required to perform these procedures competently when compared with mesh for SUI. Based on the enormous success of the mid-urethral sling, the FDA granted more than 100 510(k) exemptions for mesh “kits” to be used in the surgical management of POP (U.S. Food and Drug Administration, 2013). With use of the initial technique of transobturator access, the trocars and mesh grafts were modified to facilitate multicompartiment POP repair. This resulted in larger grafts being inserted or tunneled to the SSL, iliococcygeus fascia, arcus tendineus, obturator internus, levator ani, and perineal body. To accomplish this, considerably more vaginal dissection through wider incisions is required. Wider vaginal flaps can be more prone to “breakdown,” resulting in mesh exposure. Fluid accumulation or bleeding from deep dissection as well as tension or buckling of the mesh sheets may adversely affect graft incorporation, leading to an exposure, erosion, or pain. Tacking or tunneling of larger volumes of mesh into the deep pelvic musculature may lead to neuromuscular dysfunction of the levator ani complex and subsequent pelvic floor dysfunction. Lastly, some surgeons who were not performing transvaginal tissue-based prolapse repairs may have started performing these procedures as an “extension” of the transobturator technique. It is very clear that much more advanced dissection skills and techniques are required when performing a mesh-based prolapse repair

versus a mid-urethral sling. There is no doubt that a number of high-volume accomplished vaginal surgeons are performing mesh-based prolapse repairs safely on their patients (Murphy et al, 2012). But it is not all just about experience of the surgeon. There should be little dispute that the volume, techniques of dissection, and location of the mesh for POP repairs are associated with a risk profile that is much greater than that of the mid-urethral sling and that these procedures are vastly different—even with the same type of mesh.

Outcomes data comparisons also reveal disparity between these two procedures. With the first-generation mid-urethral sling, the efficacy and safety have been demonstrated worldwide through multiple studies with little dispute (U.S. Food and Drug Administration, 2013). Thus, these procedures are a clear (and often preferred) option in the surgical treatment of SUI. The same cannot be said for POP repairs. Most would agree that anatomic outcomes appear better in the anterior compartment (Maher et al, 2013a). However, the data are less compelling in the posterior compartment and apex. When subjective outcomes and reoperation rates are included, the data regarding mesh for prolapse are less clear—distinctly opposite from the first-generation mid-urethral sling (U.S. Food and Drug Administration, 2013). Thus the precise indications for TVM for prolapse are much less clear. A Public Health Notification is an important message from the FDA Center for Devices and Radiological Health to the health care community (Schultz, 2008). This message describes a risk associated with the use of a medical device and provides recommendations to avoid or reduce the risk. In October 2008, the FDA released a public health statement that “serious complications are associated with transvaginal placement of surgical mesh in repair of pelvic organ prolapse and stress urinary incontinence.” This report was designed to alert health care practitioners of complications associated with transvaginal placement of surgical mesh to treat POP and SUI. This report stated that over 3 years the FDA received more than 1000 reports from nine surgical mesh manufacturers of complications that were associated with surgical mesh devices used to repair POP and SUI. As a result, a number of recommendations were made to physicians, which included obtaining specialized training for each mesh placement technique and informing patients that implantation of surgical mesh is permanent. It was also recommended to inform patients about the potential for serious complications and their adverse effect on QoL. As part of this notification, the FDA embarked on additional investigations into mid-urethral sling and POP procedures using mesh, which resulted in an update of the Public Health Notification in 2011 (U.S. Food and Drug Administration, 2011b). This update was to inform the public once again regarding serious complications related to the use of TVM in POP. **Of note, the 2011 notification was regarding POP only, and did not include SUI.** In 2013, the FDA released additional findings regarding the use of mesh for SUI and POP (U.S. Food and Drug Administration, 2013). In the area of mesh for SUI, the FDA concluded that the “safety and effectiveness of multi-incision slings is well-established in clinical trials that followed patients for up to 1 year. Longer follow-up data is available in the literature, but there are fewer of these long-term studies compared to studies with one-year follow-up.” The FDA also concluded that mesh “sling surgeries for SUI have been reported to be successful in approximately 70 to 80 percent of women at one year, based on women’s reports and physical exams ... and that the vaginal exposure of mesh occurred in 2% of cases.”

This is distinctly different from the conclusions regarding the use of TVM for POP, wherein the FDA concluded that “complications are not rare ... and are of serious concern ... and that there is no clear benefit to using mesh in the transvaginal correction of POP.” These conclusions led the FDA to recommend changing the classification of TVM to Class III devices and to require extensive premarket testing on any new mesh kits for prolapse, and lastly to require 522 postmarket surveillance studies comparing TVM with tissue-based repairs to demonstrate safety and efficacy of TVM for prolapse. During this period, any prolapse kits using mesh currently available will still be able to be used by surgeons. In contrast, the FDA did not reclassify TVM for the sling in the treatment of SUI.

No premarket data or postmarket 522 data will be required for the first-generation mid-urethral sling procedures (retropubic and obturator) (U.S. Food and Drug Administration, 2011a). **Based on these observations, it is clear that the FDA concluded that the benefit-risk ratio of the first-generation mid-urethral slings was clearly favorable and did not recommend any alteration in their use.** To be clear, the FDA did require postmarket 522 studies of the second-generation mini-slings because of concerns that these procedures have inferior efficacy compared with retropubic or transobturator slings (U.S. Food and Drug Administration, 2013).

Subsequently, a plethora of legal actions has occurred based on the FDA activity regarding vaginal mesh. Multiple class action lawsuits have been organized against the manufacturers of mesh used for the treatment of SUI and POP. Millions of dollars have already been awarded, and this figure will likely rise exponentially. Several large companies have decided to withdraw their mesh products for POP from the market place. There is an infiltration of the media regarding class action lawsuits against mesh manufacturers, which has resulted in a global negative bias regarding mesh for the treatment of SUI and POP. Some of these advertisements contend that the mesh is “defective” and has been “recalled.” These claims are not congruent with the FDA findings and have also created concern in many women who have been successfully implanted with vaginal mesh—seeking removal of the “defective mesh.”

To date, there has been no recall or clinical evidence of defective mesh. In fact, the FDA action of allowing continued use of these products while postmarket surveillance is ongoing demonstrates that the FDA did not conclude that these products are defective. Also, the continued inclusion of the mid-urethral sling in these advertisements is in direct opposition to the FDA findings and level I evidence from NIH-sponsored clinical trials, which demonstrate that mid-urethral sling procedures are safe and effective.

So, where does this leave clinicians of today? We are in an environment of having to deal with the realities of POP and SUI QoL disturbances and recurrences after native tissue repair in our patients who are now anxious and likely have a very negative bias against mesh. These realities exist with almost nonexistent high-quality, comparative evidence in the area of POP. What can we do to appropriately counsel and guide our patients regarding surgical procedures that are best for them? It is clear that these answers do not exist, and comparative trials as well as registries are desperately needed to guide us through this process.

In an effort to aid surgeons, the following recommendations are offered with the goal of safe, judicious, and effective use of vaginal mesh for SUI and POP.

- **Patients should be counseled extensively regarding the mesh procedure(s) recommended.** They should be informed that they are getting mesh (and why it is best for them), that there are nonmesh alternatives, and that there are complications that do occur that are unique to mesh. They should be informed that these complications may be permanent and may require more than one operation, which may or may not correct the problem. Patients should also be informed that the most common complication unique to mesh is mesh exposure, which may be asymptomatic or may require a surgical revision, which may address the problem.
- **Clinicians should refer patients to the manufacturer’s website regarding the specific procedure for them.** They should be encouraged to learn more about their procedure in advance of the surgery. **Clinicians should refer patients to the FDA website regarding the FDA vaginal mesh communication** and also to the websites of subspecialty societies (AUA, SUFU) that contain consensus statements and other links regarding vaginal mesh.
- **Clinicians should maintain the strong distinction between mid-urethral sling procedures (retropubic and obturator) and TVM procedures for POP.** Patients should be informed of the FDA actions, which were vastly different between the two procedures, and that there is prospective NIH research demonstrating the safety and efficacy of the mid-urethral sling. Although the litigation involves all procedures, patients should be informed that the currently available evidence demonstrates the safety and

efficacy of the mid-urethral sling, making it the standard surgical treatment for SUI.

- **Widespread, routine use of TVM—particularly for primary procedures—should be discouraged in patients with POP.** Because the current evidence of TVM for POP is much more limited and the indications far less clear, the American College of Obstetricians and Gynecologists (ACOG) and American Urogynecologic Society (AUGS) position statement reflects a balanced use of mesh for POP that should be considered by all surgeons. This statement recommends reserving the use of vaginal mesh in the surgical repair of POP to women at high risk “in whom the benefit of mesh placement may justify the risk.” These women include those with recurrent prolapse—particularly of the anterior compartment—and those with medical comorbidities that “preclude more invasive and lengthier open and endoscopic procedures” (*Committee on Gynecologic Practice, 2011*).
- **Surgeons performing TVM procedures should be proficient in reconstructive pelvic surgery using native tissue techniques and should have a thorough understanding of pelvic floor anatomy as well as the complications that can occur after pelvic floor surgery.** Mesh techniques are an adjunct to perform pelvic floor procedures in properly selected patients. Mesh procedures are not “new procedures” to treat POP and SUI. In other words, if a pelvic surgeon has not performed SSL dissections and/or fixation, he or she should not be performing mesh kit procedures requiring similar dissection. Obtaining proficiency in these surgical skills should precede any introduction of apical mesh kit procedures. Institutions should be cautious to grant privileges to surgeons performing TVM procedures for prolapse who do not have preexisting credentials to do pelvic floor surgery.
- **Surgeons should be vigilant in assessing patient complaints.** Patients must be reassured that any postoperative concern is not dismissed. Surgeons should directly address these concerns and offer assistance in second-opinion referrals in the absence of an explanation. With the current uncertainty and negative perceptions of mesh, patients need reassurance that their concerns are adequately addressed and that reasonable attempts are being made to address them.
- **Surgeons should endorse and participate in prospective, comparative clinical trials as well as registries to advance the knowledge of and identify best practices of TVM usage.**

ACKNOWLEDGMENT

The authors would like to thank Joanna Togami, MD, and Christopher Chermansky, MD, who have made substantive contributions to the design and content of this chapter. Their efforts should be recognized, and are greatly appreciated.

The Evolution of Slings

Preoperative Assessment

Alternative Treatment Options

Pubovaginal Slings

Midurethral Slings

Regulatory and Legal Issues Related to Sling Mesh Complications

THE EVOLUTION OF SLINGS

Urethral slings are currently the procedure of choice for the surgical correction of female stress urinary incontinence (SUI). A variety of materials (autologous, allograft, xenograft, and synthetic) and techniques have been pursued for sling placement. The concept of slings for urethral support was first introduced in 1907 by D. Von [Giordano \(1907\)](#) as a gracilis muscle graft wrapping around the urethra ([Aldridge, 1942](#)). Later, German surgeons used slings fashioned from muscle and fascia in children with incontinence ([Goebell, 1910](#)). The rectus abdominis muscle and fascia were first used to treat SUI by [Frangenheim in 1914](#) and then later modified by Albert [Aldridge in 1942](#) ([Frangenheim, 1914](#); [Aldridge, 1942](#)). It was Aldridge who first theorized that the abdominal muscles' response to increased intra-abdominal pressure could be used anatomically to compress the urethra. In his operation, Aldridge used a 1.5- × 6-cm strip of rectus fascia that was left attached to the aponeurosis of the rectus abdominis muscle in the midline (only the two ends were mobilized) and then passed under the urethra, where the free ends of the sling were then sutured together. Aldridge left the sling attached to the rectus fascia in the midline because he theorized that this would allow the sling to compress the urethra when the abdominal muscles responded to increases in intra-abdominal pressure. Aldridge stated that he came up with this "fundamental principle" by reading a case report of a surgery performed by Phillip [Price in 1933](#), who used a fascia lata sling passed around the urethra and attached to the rectus muscle to cure the incontinence of a woman with congenital absence of the sacrum and coccyx ([Price, 1933](#)). In this article, Price stated that by attaching the sling to the rectus muscle he was able to take full advantage of changes in the patient's posture and position to tighten or relax the sling at times when incontinence is most likely to occur. Although the technique described by Price was very similar to modern autologous pubovaginal sling (PVS) surgery, we now know that with healing and incorporation, the sling becomes fixed and immobile in the retropubic space and continence is not related to the fact that it is secured over the rectus abdominis muscle fascia. Anecdotally, this is proven by the fact that cutting these securing sutures in a patient with an obstructive sling months after surgery will not release tension.

In 1956, [Jeffcoate](#) used Aldridge's technique on 40 women and reported an 86% cure rate. However, it was McGuire's modifications and subsequent use of the PVS in patients in whom prior retropubic suspensions and anterior colporrhaphies had failed, with a cure rate of 91% that reintroduced and popularized the procedure ([McGuire and Lytton, 1978](#)). Then in 1988, [Blaivas and Olsson \(1988\)](#) used McGuire's technique in their description of the modern PVS placed at the bladder neck, in an effort to correct urethral hypermobility

and modify the pressure transmission invoked by intra-abdominal pressure changes.

Later theories regarding the causes of incontinence focused on urethral hypermobility as the primary cause of SUI. In this model the abnormally low location of the bladder neck in patients with SUI resulted in unequal intra-abdominal pressure transmission to the bladder and urethra. In 1994, [DeLancey](#) published a revised model that made a significant contribution to the current understanding of the continence mechanism. [DeLancey's proposal](#) was that in healthy individuals, a "suburethral hammock" attached laterally supports the urethra, but that in patients with SUI there is a deficiency of this supporting layer that is evidenced by hypermobility of the bladder neck and urethra ([DeLancey, 1994](#)). It was theorized that descent of these structures inferiorly allowed for unequal pressure transmission and subsequent SUI. Therefore a PVS placed at the bladder neck is able to improve SUI by providing a layer of tissue that compresses the urethra during times of increased intra-abdominal pressure. This and similar theories emphasize that urethral support is derived from attachments to the arcus tendineus fasciae pelvis (ATFP) and levator ani muscles.

From 1991 to 1998 the PVS had surpassed needle-type suspensions and anterior urethropexies to become the predominant invasive surgical method for the treatment of SUI in the United States ([Anger et al, 2009](#)). Then in 1998 the U.S. Food and Drug Administration (FDA) approved the first midurethral sling (MUS) for use in patients with SUI, and the rate of sling surgery increased by more than threefold (78.3 to 237.4 per 100,000 person-years) ([Jonsson et al, 2012](#)). Unfortunately, as with most national databases, Medicare data are limited by the fact that the Common Procedural Terminology (CPT) codes do not reveal the exact type of sling that is placed. However, many authors have speculated and inferred that the dramatic acceleration in sling surgeries is most likely a result of the increased popularity of the MUS ([Oliphant et al, 2009](#); [Wu et al, 2011](#)).

Unlike the PVS, the MUS should be placed loosely at the midportion of the urethra. Placement of the MUS at this location is partially based on the theories initially espoused by Ingelman-Sundberg (1953). These researchers noted that the pubococcygeal muscles insert at the level of the midurethra just outside the vaginal epithelial wall and play a vital role in the midurethral continence mechanism. They further propounded that this anatomic finding is important when considering methods to correct urinary incontinence. Decades later, Westby and colleagues (1982) and [Asmussen and Ulmsten \(1983\)](#) demonstrated that in women who are continent, maximum urethral closure pressures (MUCPs) occur at the midurethra and that this phenomenon is most likely caused by the confluence of anatomic structures in that area.

Based on the aforementioned theories and other published experiments, in 1990 **Petros and Ulmsten** proposed a unifying concept called the *integral theory*. They stated that the most important factors to preserve continence were adequate function of the pubourethral ligaments, the suburethral vaginal hammock, and the pubococcygeus muscle. They postulated that injury to any of these three components from surgery, parturition, aging, or hormonal deprivation could lead to impaired midurethral function and subsequently urinary incontinence. **Ulmsten and colleagues** published one of numerous studies used as the basis for the integral theory in 1987. In that paper, the researchers performed biopsy of the skin and round ligament of eight continent women and seven incontinent women and found that the tissues of incontinent women contained 40% less collagen. From this information, the authors concluded that weakness of the connective tissue supporting the urethra secondary to the loss of collagen might contribute to incontinence.

In 1995, **Ulmsten and Petros (1995)** applied the integral theory to the development of the first retropubic synthetic MUS, which they termed an *intravaginal slingplasty*. In this initial paper, Ulmsten and Petros reported that they completely cured incontinence in 39 of 50 (78%) women who underwent the intravaginal slingplasty and that there were no complications. In 1998, **Ulmsten and colleagues** had changed the name of the procedure to *tension-free vaginal tape (TVT)* and reported the results of a prospective multicenter study looking at this surgical technique's safety and efficacy. In that study, 119 of 131 (91%) patients were cured of their incontinence. In terms of complications, 2 patients developed transient urinary retention, 2 patients developed hematomas, 1 patient developed persistent urinary retention that required "a small adjustment" via a vaginal incision, 1 patient experienced mesh perforation of the bladder that was recognized at the time of surgery (mesh was replaced), and, although it is unclear if there was vaginal mesh exposure, 1 patient developed a wound infection that required a minor surgical procedure and vaginal estrogen. It is interesting to note that this first multicenter trial of MUS surgery may have also been the first to report two of the now well-known unique and troublesome complications of MUS surgery: mesh perforation of the urinary tract and mesh exposure.

For several years the retropubic approach was the only published method of placing a tension-free MUS, but in 2001, **Delorme** described the first transobturator approach. In that study, 39 of 40 patients were cured of their incontinence and only 1 patient experienced a complication. The authors commented that unlike the retropubic MUS, this new approach did not violate this surgical plane that lies in close proximity to the bladder and therefore decreased the risk of bladder or bowel injury. Initially, many proponents of the transobturator sling believed that there was no need to perform a cystoscopy after trocar passage; however, the American Urological Association (AUA) guideline states that a cystoscopy can be performed to minimize the risk of mesh urinary tract perforation (**Appell et al, 2009**). Ten years after the introduction of the MUS, **Richter and colleagues (2010)** published a study demonstrating that retropubic and transobturator MUSs were equally efficacious and generally safe.

The most recent step in the evolution of the sling came in 2006 with the FDA approval of the first single-incision MUS (TVT Secur, Ethicon Endo-Surgery, Somerville, NJ) (**Abdel-Fattah et al, 2011**). Data are less robust for the single-incision slings (mini-slings) and this will be discussed later in the chapter. Similar to transobturator slings, the risk of bladder or bowel injury is low with single-incision slings; however, cystoscopy is recommended in general to rule out bladder or urethral injury.

Over the past 10 years, numerous studies have continued to demonstrate the efficacy and safety of all different types of sling procedures for the treatment of SUI. However, recently, regulatory and professional organizations have raised concerns about mesh exposure and perforation complications unique to synthetic mesh materials, biologic grafts, and the specialized tools used to place them (**Novara et al, 2008**), prompting initial warnings from the FDA. Most of these concerns are related to graft materials used in

transvaginal pelvic organ prolapse surgery, although suburethral slings were implicated by technical similarities. In 2010, the International Urogynecological Association (IUGA) and the International Continence Society (ICS) released a report clarifying and standardizing the terminology related to complications from insertion of synthetic and biologic materials during female pelvic surgery (**Haylen et al, 2011**). According to that report, synthetic mesh is termed a *prosthesis* and a biologic implant is termed a *graft*. Mesh located in the lower urinary tract is termed a *perforation*, and extrusion of mesh through the skin or vagina is termed *exposure*. This topic is of great importance to pelvic surgeons and their patients and will be discussed in further detail later in this chapter.

KEY POINTS: EVOLUTION OF SLINGS

- Early theories regarding the cause of stress incontinence were focused on the unequal transmission of pressure to the bladder and urethra, urethral hypermobility, and the abnormal inferior location of the urethra.
- Later theories emphasized the importance of three separate components that support the proximal and midurethra (pubourethral ligaments, the suburethral vaginal hammock, and the pubococcygeus muscle).
- Based on these theories, PVSs are placed under mild tension at the bladder neck to reestablish the suburethral hammock, and MUSs are placed loosely at the midurethra to prevent movement of the posterior urethral wall.

PREOPERATIVE ASSESSMENT

The AUA guideline for the surgical management of female SUI states that the goal of a diagnostic evaluation in a woman with incontinence is to characterize the type of incontinence, assess underlying comorbid medical conditions, elucidate the differential diagnoses, and discover prognostic information that will aid in the selection of treatment (**Appell et al, 2009**). The evaluation of urinary incontinence begins with a thorough history focused on the onset, frequency, character, and severity of the incontinence and other voiding symptoms. Some clinicians may find that a validated questionnaire and a voiding diary best accomplish this step. It is also important to reveal factors that worsen the patient's incontinence such as sexual intercourse. It is also critical to accurately assess the degree of a patient's urgency because this symptom has been shown to correlate with worse outcomes after sling surgery (**Richter et al, 2008**). The rest of the history should be dedicated to evaluation of other factors that can affect bladder and urethral function such as neurologic diseases, medications, and prior surgeries. Also, it is important to query the patient about problems related to fecal incontinence or defecation. Knowledge of prior radiation is also useful because radiation may compromise the quality of a rectus fascial graft.

A focused neurourologic examination and pelvic examination should be performed on any patient with complaints of urinary incontinence. Uncovering physical findings of a neurologic or musculoskeletal disorder may aid in the treatment of a patient's incontinence symptoms. The pelvic examination should be performed to evaluate for any correctable anatomic abnormalities that can contribute to incontinence such as a vesicovaginal fistula and any abnormalities that are the result of urinary incontinence such as vaginal epithelial irritation. Using both resting state and provocative maneuvers (i.e., Valsalva and coughing) the examination should evaluate vaginal anatomy, including the urethral meatus and vaginal support (i.e., pelvic organ prolapse); quality of vaginal tissues, including the presence of tissue atrophy and irritation; the presence of urinary incontinence, including the degree of urethrovesical hypermobility; and any other associated findings, such as the presence of fistulae, foreign materials, or other anatomic abnormalities. During the examination, the patient should also be asked to perform

Valsalva maneuvers to reveal pelvic organ prolapse, urethral hypermobility, and stress incontinence. Although the usefulness of this test is controversial, a Q-tip test can also be performed to assess abnormal mobility of the urethra. With this test a patient is considered to have urethral hypermobility if a Q-tip inserted into the urethra moves more than 30 degrees during abdominal straining (Bergman and Bhatia, 1987). Lastly, if a supine stress test with a full bladder does not demonstrate urinary incontinence, then a standing stress test is imperative.

Based on AUA guidelines, a urinalysis and measurement of postvoid residual (PVR) volume should be performed on all patients, but more extensive imaging is not part of the routine evaluation of urinary incontinence. However, in some patients abnormal findings in the history, physical examination, or urinalysis may warrant this type of further evaluation. For example, the initial presentation of undiagnosed neurologic conditions such as multiple sclerosis or central nervous system tumors may manifest with urologic symptoms; therefore, in these patients, magnetic resonance imaging (MRI) of the head, spine, and pelvis for spinal cord or brain lesions could prove beneficial.

Although the value of urodynamics in predicting outcomes after sling surgery is debatable (Nager et al, 2008, 2011), according to the AUA guideline for SUI surgery, urodynamics and cystoscopy are indicated in any patient in whom a definitive diagnosis of stress incontinence is unclear or when there are concomitant overactive bladder (OAB) symptoms, a history of prior lower urinary tract surgery, the possibility of neurogenic bladder, a negative stress test result, an unexplained abnormality on urinalysis, a high PVR volume, grade 3 or greater prolapse, and evidence of dysfunctional voiding (Appell et al, 2009). Obviously this step of evaluation is dependent on the willingness of the patient to undergo the studies and the impact that further evaluation will have on treatment options. Of note, urodynamic testing should be performed with and without a pessary if significant prolapse is present.

In the incontinent patient, the goal of urodynamics is to evaluate urethral and bladder function. In general, in patients with SUI, the abdominal leak point pressure (ALPP) and the MUCP are often used as indicators of urethral dysfunction. In 1981, McGuire looked at the urodynamic properties of patients in whom SUI operations had failed and determined that MUCP below 20 cm H₂O was indicative of type III SUI (now known as *intrinsic sphincter deficiency* [ISD]) (McGuire, 1981). Several years later, Sand and colleagues (1987) performed urodynamic studies on 86 women undergoing modified Burch colposuspensions and determined that women with MUCP of 20 cm H₂O or lower had a significantly higher failure rate (54% vs. 18%) than women with MUCP above 20 cm H₂O. Other authors have also used MUCP of 20 cm H₂O or lower to characterize a patient with severe urethral dysfunction (Clemons and La Sala, 2007; Fritel et al, 2008).

In addition to MUCP, ALPP can also give the clinician a general sense of the severity of SUI. ALPP has been used as an indicator of urethral dysfunction since this relationship was first described by McGuire and colleagues (1993). In this initial study, the authors performed urodynamic studies on 125 women with SUI and determined that ALPP below 60 cm H₂O signified ISD, and ALPP above 90 cm H₂O signified no or very little ISD. The definition of ISD has evolved from one based on strict urodynamic criteria to a clinical diagnosis. In understanding surgical treatment, it is essential to appreciate that all women with stress incontinence have some component of ISD.

In addition to the evaluation of the urethra during urodynamic studies, assessment of bladder pressure during filling and emptying yields valuable prognostic information about bladder function. Most important, the discovery of detrusor overactivity (DO) during evaluation of incontinence may have an impact on deciding the appropriate treatment options. Although it has been theorized that both the stress leakage of urine into the urethra (Kuru, 1965) and the traction on pelvic nerves that occurs when increased abdominal pressure is applied to weakened pelvic supportive tissue (Serels et al, 2000) can induce DO, other treatment options should be considered before proceeding with sling surgery in patients with

DO because stress-induced DO may be difficult to treat with a sling alone. Abnormally small bladder capacity and decreased compliance may also negatively affect the outcomes of sling surgery, and these factors should also be considered.

KEY POINTS: PREOPERATIVE ASSESSMENT

- At minimum, women being evaluated for urinary incontinence should undergo a focused history and physical examination characterizing the patient's symptoms, confirming SUI, and excluding complicating factors. In addition, basic clinical tests such as urinalysis and a PVR volume measurement should be performed.
- Urodynamic studies are not needed in all patients before SUI treatment; however, such studies may prove useful if the diagnosis of stress incontinence is unclear or when there are complicating factors, such as concomitant bladder storage and voiding symptoms, prior lower urinary tract surgery, the possibility of neurogenic bladder, a negative stress test result, an unexplained abnormality on urinalysis, or significant pelvic organ prolapse.
- Although slings are an effective treatment for both genuine stress urinary incontinence (GSI or genuine SUI) and mixed urinary incontinence (MUI), a thorough understanding of preoperative symptomatology will help guide counseling and treatment decisions.

ALTERNATIVE TREATMENT OPTIONS

In most cases of incontinence, surgery should not be considered until more conservative management has failed. Initial conservative therapy includes patient self-awareness and education, dietary modification, fluid restriction, weight loss, and pelvic floor muscle training (Dalloso et al, 2003). There is significant evidence in the literature to support these methods of treatment (Osborn et al, 2013). A 2009 study by Subak and colleagues of 338 obese women randomized to one of two different weight loss programs highlighted the importance of weight loss. After 6 months, the two programs showed an average 8- and 1.6-kg weight loss with a corresponding significant 58% and 33% reduction in SUI. Another conservative treatment option is pelvic floor muscle training (Kegel exercises). These are theorized to help with pelvic floor muscle strength and coordination. A Cochrane Database systematic review by Dumoulin and Hay-Smith (2008) of 13 randomized and quasi-randomized trials of pelvic floor muscle training in patients with SUI concluded that pelvic floor muscle training should be recommended to most patients with SUI before surgical treatment. In addition to lifestyle modification and pelvic floor muscle training, pessaries and other devices have been shown to help with SUI in select individuals (Staskin et al, 1998; Robert and Mainprize, 2002).

The submucosal injection of periurethral bulking agents through a cystoscope into the urethra is a minimally invasive, mildly successful treatment for SUI. The recent discontinuation of bovine-derived cross-linked collagen by its manufacturer has led to the increased use of several newer synthetic agents. However, both a Cochrane review (Kirchin et al, 2012) and a review by the Fourth International Consultation on Urinary Incontinence (Abrams et al, 2010) of periurethral bulking agents concluded that there was limited evidence for the benefit of these agents. Nevertheless, because of the low risk of side effects, periurethral bulking agents are still a good option for many patients who are not ready to undergo a more invasive surgical procedure.

PUBOVAGINAL SLINGS

PVSs (slings at the bladder neck as distinct from MUSs) are highly versatile for the treatment of uncomplicated and complicated

urinary stress incontinence. PVSs are indicated for treatment of incontinence associated with a deficiency in a portion of the midurethral complex, hypermobility, ISD, MUI, concomitant cystoceles (Cross et al, 1997; Serels et al, 1999), urethral diverticula, and neurologic conditions (Austin et al, 2001). More specifically, in neuropathic patients, such as those with myelodysplasia, PVSs are indicated for the SUI that may occur between clean intermittent catheterizations (CICs) (once a thorough urodynamic evaluation of compliance and bladder capacity is completed). PVSs also aid in the reconstruction of the urethra after damage secondary to trauma, synthetic mesh (or graft) perforation, and iatrogenic hypospadias, or they can be used for interposition during urethral repairs of urethrovaginal fistulae or urethral diverticula (Gormley et al, 1994; McGuire and O'Connell, 1995; Blaivas and Heritz, 1996; Leng and McGuire, 1998). PVSs are also indicated for recurrent SUI after failed retropubic suspensions or MUS placement (Beck et al, 1988; Petrou and Frank, 2001). Although many different sling materials and techniques have been developed, the PVS using autologous fascia is the gold standard for management of ALL forms of SUI.

Anatomy and Mechanics of a Pubovaginal Sling

Female SUI is caused by a combination of damage to the midurethral complex and ISD. Urethral hypermobility is a physical indication that the midurethral complex is not working properly. The female urethra lies under the pubic symphysis, and the pubourethral ligaments suspend the anterior urethral wall to the pubic arch. In cases of urethral hypermobility, Valsalva or other stress maneuvers cause the posterior wall of the urethra to slide away from the anterior urethral wall and in turn open the bladder neck and proximal urethra. Uneven pressure transmission combined with the opening of the bladder neck (funneling) cause a loss of urine with stress maneuvers. ISD arises from defects within the urethra proper, so that the urethral sphincter is unable to coapt and generate enough resting urethral closing pressure to maintain continence.

The female urethra is composed of four separate tissue layers that assist in keeping it closed. Compression from the middle muscular layer helps to maintain the resting urethral closure mechanism, and the outer seromuscular layer augments this closing pressure. In normal circumstances, the resting urethral closing pressure of the internal sphincter exceeds the resting or Valsalva pressure exerted by the bladder. In addition, fast-twitch fibers of the external sphincter are responsible for a sudden voluntary contraction and slow-twitch fibers provide continuous passive control by the involuntary guarding reflex during bladder filling. In addition to these structures, the integrity of the pelvic diaphragm is also dependent on the levator ani for continence control. Lastly, the urethropelvic ligament and pubocervical fascia provide support to the bladder neck and undersurface of the bladder, respectively, to prevent SUI (Vasavada and Rackley, 2009).

The PVS is positioned at the bladder neck to provide urethral compression without obstruction during times of increased intra-abdominal pressure. The ultimate goal is to provide adequate urethral coaptation and increase urethral responsiveness to abdominal pressure. This must be balanced against the risks of ischemia, retention, and erosion from unnecessary tension. Aldridge's (1942) earliest anatomic descriptions left the sling attached to the rectus fascia in the midline. This limits sling mobility and provides no method for avoiding excess tension, often resulting in outlet obstruction. In addition, the sling is often too short to completely pass under the urethra. McGuire and Lytton (1978) modified this technique with a longer, 12-cm strip of rectus fascia that remained attached to the rest of the rectus fascia laterally on one side. Again, this technique was limited because with one side attached there was also no way to adjust the tension. The present concept of the PVS comes from Blaivas and Olsson (1988), who modified McGuire's technique by using a shorter free graft of rectus fascia whose tension could be adjusted. It is the incorporation of the sling into the endopelvic fascia and subsequent fibrosis, and not entry into the retropubic space, that prevents SUI. Incorporation of the sling into the endopelvic fascia and eventual fixation of the sling in the retropubic

space prevents it from responding to changes related to the abdominal musculature, contrary to the theory earlier described by Aldridge and previous surgeons. The width (2 to 3 cm) of the PVS ensures that there is sufficient support to provide the needed urethral compression and a cross-sectional area adequate to avoid the formation of a narrow constricting band. The ideal PVS material requires longevity and durability to allow for strong sling scaffolding, and the material should be incorporated and remain intact, with limited tissue reaction.

Pubovaginal Sling Materials

Autologous, allograft, xenograft, and synthetic materials have been used for the construction of a PVS. The ideal material provides long-lasting suburethral support with minimal complications. Ideally, implanted materials should be incorporated into the host with minimal tissue reaction. In reality, most materials promote organized fibrosis and reinforce the sphincteric mechanism through improved suburethral support. Theoretically, a greater degree of fibrosis leads to better clinical results (Bidmead and Cardozo, 2000; Woodruff et al, 2008). Yet, inflammatory infiltration can lead to rapid sling material degradation and possible tissue destruction with erosion (Bidmead and Cardozo, 2000). Although there is complete biocompatibility of the autologous sling and negligible urethral perforation, biologic graft and synthetic prosthetic materials have been increasingly used to decrease operative time, morbidity, pain, and hospital stay (Niknejad et al, 2002).

Pubovaginal Sling Autologous Graft Materials

The most commonly used autologous materials are rectus abdominis fascia harvested from the abdominal wall and fascia lata harvested from the lateral thigh. Fitzgerald and colleagues (2000) reported that after sling placement, rectus fascial grafts undergo extensive remodeling and have abundant fibroblasts and connective tissue on biopsy specimens. Other authors have published similar findings. In 2008, Woodruff and colleagues performed a histologic comparison of PVS materials (10 synthetic, 5 autologous, 5 allograft, and 4 xenograft) and noted that the greatest degree of host fibroblast infiltration and neovascularization with minimal inflammatory or foreign body reaction was in autologous materials. Analysis of explanted specimens up to 65 months after placement revealed that the autologous fascial grafts were consistently intact and displayed grossly only a small amount of degradation. In addition to the value of minimal tissue inflammation, autologous tissue is also beneficial because of the negligible risk of urethral erosion (Webster and Gerritzen, 2003). However, disadvantages include increased operative time, hospital stay, postoperative pain, risk of suprapubic wound seroma, and risk of incisional hernia (Gomelsky and Dmochowski, 2003).

It is important to note that even if the rectus fascia harvest site is scarred and thickened from prior operations, this does not compromise its usefulness for PVS placement. Nevertheless, there are some instances, such as a prior ventral hernia repair, in which fascia lata is the preferred autologous material for PVSs. This fascia is harvested from the thigh and has similar properties to rectus fascia (Beck et al, 1988; Latini et al, 2004). Like rectus fascia, fascia lata is completely biocompatible and is associated with minimal tissue reaction. Unlike rectus fascia, the recovery time is less and there is no risk of future abdominal hernia formation. However, it does require repositioning of the patient, increased operative time, and operating in an area unfamiliar to most pelvic surgeons (Govier et al, 1997). In 1997, Wheatcroft and colleagues reported that 67% of their patients had pain on walking for 1 week after fascia lata harvest surgery (Wheatcroft et al, 1997). Latini and coworkers (2004) reported that only 7% of patients complained of pain at incision site 1 week after surgery in their series using a Crawford fascial stripper. Thigh muscle herniation has also been reported in the literature, but this appears to only occur when large strips of fascia are removed (Dubiel and Wigren, 1974; Wheatcroft et al, 1997). In these studies the rate of thigh herniation was 51%

(20 of 39) with a 10- × 20-cm fascial graft and 0% (0 of 24) with a 1.5- × 12- to 15-cm fascial graft.

Vaginal epithelium has also been used as an autologous tissue. [Raz and colleagues \(1989\)](#) described use of in situ vaginal wall for autologous sling material. However, this tissue may lack sufficient tensile strength, and there is a risk of epithelial inclusion cyst formation and vaginal shortening. Also a lack of retropubic space dissection may militate against overall efficacy of this procedural variety ([Raz et al, 1989](#); [Ghoniem and Hassouna, 1998](#); [Loughlin, 1998](#); [Appell, 2000](#)).

Pubovaginal Sling Allograft Materials

Biologic and synthetic graft materials have been increasingly used to decrease operative time, morbidity, pain, and hospital stay. Cadaveric allografts used in many nonurologic surgical arenas (e.g., orthopedics, neurosurgery) were eventually adopted for SUI. **Allograft slings are currently derived from either cadaveric fascia lata or acellular human dermis.** After harvest, the allografts are processed by solvent dehydration or by lyophilization (freeze-drying) to remove genetic material and to prevent the transmission of infectious agents. Secondary sterilization may also be achieved by gamma radiation ([Gomelsky et al, 2003](#)). Unlike with autologous material, histologic analysis reveals that cadaveric dermis has minimal host fibroblast infiltration and neovascularity, particularly in central aspects of the graft ([Woodruff et al, 2008](#)). In addition, gross examination revealed disruption of the sling scaffold and significant thinning and degradation of the graft.

In general, **allografts are pliable, easy to use, and available in a variety of sizes.** Furthermore, **no specific allograft has shown a clinical advantage in use;** however, acellular dermis rehydrates in 0.9% saline more quickly than does cadaveric fascia lata (5 minutes vs. 15 to 30 minutes) ([Gomelsky et al, 2003](#)). In addition, biomechanical studies have shown that solvent-dehydrated cadaveric fascia lata and acellular dermis have a higher maximal load failure than freeze-dried cadaveric fascia lata ([Hinton et al, 1992](#); [Lemer et al, 1999](#)). More specifically, [Lemer and colleagues \(1999\)](#) prospectively studied the maximum load failure and stiffness of autologous rectus fascia versus freeze-dried fascia versus solvent-dehydrated fascia and cadaveric dermal grafts. The mean values for maximum load to failure, maximum load graft width, and stiffness were all significantly lower for the freeze-dried fascia lata group compared with the autologous, solvent-dehydrated, and dermal graft groups. Lemer and colleagues theorized that ice crystal formation produced by tissue freezing disrupts the collagen matrices and causes decreased tissue integrity and durability. Dermal grafts differ from fascial allografts because they are derived from skin that is processed to eliminate the epidermis and all immunogenic cellular elements. Dermal grafts provide a protein matrix that serves as a collagen scaffold for the host's own cellular matrix.

Because they are harvested from cadavers, allografts raise the concern of potentially transmitting illnesses such as the human immunodeficiency virus (HIV), hepatitis, and Creutzfeldt-Jakob prion disease (CJD). Since the onset of screening in 1985, there has been one documented case of HIV transmission from a tissue transplant. The estimated risk of acquiring tissue from a properly screened donor infected with HIV is 1 per 1,667,600 ([Gallantini and Cespedes, 2002](#)). A few cases of CJD have been reported after transplantation of cadaveric dura or corneas; however, skin obtained from animals infected with these prions has demonstrated no detectable infectious particles. Currently, the theoretic risk of developing CJD from non-neural allograft is 1 in 3.5 million. No cases of hepatitis or CJD have ever been attributed to the use of processed cadaveric fascia or dermis ([Amundsen et al, 2000b](#); [Gallantini and Cespedes, 2002](#)). Although the theoretic risk of developing hepatitis from allograft graft material is unknown, within the musculoskeletal tissue transplantation literature, two cases of hepatitis transmission have been reported. One of those was a tissue donor (cancellous chips) who transmitted HIV, hepatitis B virus, and human T-lymphotropic virus. These transmissions all occurred before the implementation of extensive donor screening for viruses and bac-

teria and the availability of serologic tests (or both) ([Shutkin, 1954](#)). In June 2002, the Centers for Disease Control and Prevention (CDC) reported a case of hepatitis C virus (HCV) transmission from minimally processed, cryopreserved patellar tendon allograft. In this case, donor screening was performed during the window period for HCV testing. Retest of the donor sample with HCV RNA testing confirmed the donor as the source once the recipient reported HCV infection 1 year after transplantation ([CDC, 2003](#); [Vangsness et al, 2006](#)). Despite the low risk of disease transmission, human DNA has been detected in various allograft materials ([Choe and Bell, 2001](#); [Hathaway and Choe, 2002](#)). The clinical significance of this is unknown.

Pubovaginal Sling Xenograft Materials

Xenografts have been used since the 1980s ([Descurtins and Buchmann, 1982](#); [Iosif, 1987](#)) because of their immediate accessibility and use with minimal morbidity. Porcine and bovine xenografts have been used as sling materials with decreasing popularity in recent years. The forms of xenograft used are **porcine dermis, porcine small intestinal submucosa (SIS), and bovine pericardium.** Modern processing techniques using diisocyanate to remove genetic material have made porcine grafts both safer and more pliable; however, in a 12-week rabbit model, there was significant loss of tensile strength after implantation ([Dora et al, 2004](#)). It is interesting to note that histopathologic analysis has shown porcine SIS to contain growth factors that may reduce host-graft immunologic reaction and lessen tissue scarring ([Wiedemann and Otto, 2004](#)). Although most data support SIS as nonimmunogenic, animal studies by [Thiel and colleagues \(2005b\)](#) suggested that an intense inflammatory reaction occurs 30 to 90 days after subcutaneous implantation. In a report by [Kalota \(2004\)](#), 6 of 18 (33%) patients experienced postoperative inflammation after an SIS PVS procedure. [Konig and colleagues \(2004\)](#) reported a single case of postoperative inflammation with abscess formation with SIS use. [Ho and colleagues \(2004\)](#) reported a similar reaction in 6 of 10 patients. In a series by [John and colleagues \(2008\)](#), all of the patients had pain and erythema at the abdominal incision, and 2 developed abscesses. Of note, 5 of the 6 patients with inflammatory responses were continent. Five patients were treated conservatively and 1 patient required abscess drainage. The exact cause of these problems is unknown but is likely related to a foreign body reaction from the multilayered (eight-ply) SIS material, a reactive manufacturing ingredient, or the tendency for suprapubic fat to produce an inflammatory reaction.

In 2001, [Kubricht and colleagues](#) showed that porcine SIS has less tensile strength than cadaveric fascia lata. Bovine pericardium is available in a preparation cross-linked with glutaraldehyde or as a non-cross-linked acellular matrix ([Gomelsky et al, 2003](#)). Histopathologic comparison of sling materials by [Woodruff and colleagues](#) revealed xenograft (porcine dermis) to have no host fibroblast infiltration, no inflammatory reaction, and no foreign body reaction ([Woodruff et al, 2008](#)). This study also showed that xenograft had the highest propensity to encapsulate. The researchers found that a capsule formed around the porcine dermis specimens, isolating the graft from the periurethral tissue. The grafts were described as appearing similar to their original appearance at time of implantation.

Pubovaginal Sling Synthetic Prosthetic Materials

In 1959, [Francis Usher](#) introduced the first synthetic biomaterial, polyethylene mesh for use in hernia surgery. In the decades since, other synthetic materials have been introduced and there has been a transition to **polypropylene** ([Amid, 1997](#)). The first synthetic sling, made of nylon, was introduced in 1953 ([Kraatz, 1953](#)). The addition of synthetic material for use in PVS surgery brought the advantages of an almost unlimited supply of artificial graft material in various sizes and shapes, consistency in quality, the elimination of harvest site complications, and decreased operative time. **Compared with biologic grafts, synthetic materials are more uniform,**

more consistent, and more durable. In addition, synthetic prosthetic materials are sterile, biocompatible, and noncarcinogenic (Niknejad et al, 2002). On histopathologic comparison, synthetic materials demonstrate the least amount of degradation or disruption and the greatest amount of fibroblast ingrowth and tissue ingrowth into the specimen (Woodruff et al, 2008). Microscopically, synthetic materials are associated with significant fibroblast infiltration and a foreign body reaction characterized by giant cells and occasional microcalcifications. This foreign body reaction is not visible grossly, and no graft disruption or adverse effects to the host occur.

Artificial graft materials do have potential drawbacks, including graft infection, urinary tract perforation, and vaginal exposure. The chemical and physical properties of each artificial material and patient characteristics determine how the sling is incorporated into the surrounding tissue and its susceptibility to infection or exposure. The susceptibility to infection in multifilament fibers is proportional to the porosity and the pore size of the materials (Amid, 1997; Niknejad et al, 2002). Tightly woven mesh provides a safe harbor for small bacteria, excluding macrophages and polymorphonuclear leukocytes. Loosely woven mesh allows tissue ingrowth and neovascularization without limiting cellular access. Tissue bonding to the mesh strengthens and supports the repair. A tightly woven and large-diameter filament mesh will tend to exhibit increased stiffness or decreased pliability, which may contribute to exposure. The classification by Amid (1997) used for synthetic materials in hernia surgery may be practically applied to urology as well (Table 84-1). The most frequently used materials are grouped into four types. Type I are totally macroporous prostheses (Trelex Natural Mesh [Boston Scientific, Natick, MA]; Marlex [C.R. Bard, Murray Hill, NJ]; Prolene [Ethicon]) containing pores larger than 75 microns, which is the pore size for admission of macrophages, fibroblasts, blood vessels, and collagen fibers (White et al, 1981; Bobyn et al, 1982; White, 1988). Type II includes totally micropo-

rous prostheses (Gore-Tex, Surgical Membrane, and Dualmesh, which are all expanded polytetrafluoroethylene [ePTFE] and manufactured by W.L. Gore and Associates, Newark, DE) containing pores less than 10 microns in at least one of their dimensions. Type III includes macroporous prostheses with multifilamentous or microporous components (polytetrafluoroethylene [PTFE]—Teflon [DuPont USA, Wilmington, DE]; braided Dacron mesh—Mersilene [Ethicon]; braided polypropylene mesh—Surgipro [US Surgical, Norwalk CT]; and perforated MycroMesh patch [W.L. Gore and Associates]). Last, type IV includes biomaterials with submicronic pore size (Silastic, Celgard [polypropylene sheeting]) (Amid et al, 1992) (Table 84-2). Amid (1997) proposed that the risk of infection and seroma formation was decreased by use of type I mesh.

The most commonly used synthetic material for PVSs is polypropylene mesh. It is composed of loosely woven strands of polypropylene and has a pore size greater than 80 μ m, permitting passage of macrophages and excellent host tissue ingrowth (Kobashi et al, 2002). This represents type I in the Amid classification. Historically, sling techniques have changed to limit the associated morbid complications. For example, synthetic material is rarely used in PVSs to pull the bladder neck into a high retropubic position because of high perforation rates (discussed later in chapter). Instead, newer approaches position sling loosely at the midurethra (discussed later in chapter) (Niknejad et al, 2002).

Pubovaginal Sling Operative Procedure

Pubovaginal Sling Patient Counseling

In addition to the normal preoperative counseling, if a synthetic prosthetic or biologic graft material is being used, surgeons should thoroughly counsel their patients about the permanent nature of these products and the unique and sometimes serious complications related to their use. In our opinion, this step is vitally

TABLE 84-1 Amid Classification for Synthetic Materials

TYPE	DESCRIPTION	BRANDS
I	Pores >75 μ m; macroporous	Trelex Natural Mesh, Marlex, Prolene
II	Pores <10 μ m; microporous	Gore-Tex, Surgical Membrane, Dualmesh (all three are ePTFE)
III	Macroporous with multifilamentous or microporous components	Teflon (PTFE), Surgipro (braided polypropylene mesh), Gore-Tex MycroMesh (perforated ePTFE patch), Mersilene (braided Dacron* mesh)
IV	Submicronic pore size	Silastic†, Celgard‡ (polypropylene Silastic laminated sheeting)

*Dacron is polyethylene terephthalate (polyester) and is manufactured by DuPont USA.
†Silastic is a silicone polymer manufactured by Dow Corning Corporation in Midland, MI.
‡Celgard is manufactured by Celgard LLC in Charlotte, NC.
ePTFE, expanded polytetrafluoroethylene.

Modified from Amid PK. Classification of biomaterials and their related complications in abdominal wall hernia surgery. *Hernia* 1997;1:15–21.

TABLE 84-2 Synthetic Pubovaginal Sling Materials

TRADE NAME	COMPOSITION	DETAILS
Mersilene	Polyethylene terephthalate	Multifilament fibers, very porous, becomes firmly embedded in native tissues
Teflon	Polytetrafluoroethylene	Multifilament
Gore-Tex	Expanded polytetrafluoroethylene	Very flexible
Silastic	Silicone plus woven polyethylene terephthalate	Minimal tissue reaction, which facilitates removal or revision if necessary
ProteGen	Synthetic mesh impregnated with collagen matrix	Removed from market secondary to high rate of vaginal extrusion
Marlex, Prolene	Polypropylene	Monofilament with open weave pattern

Modified from Niknejad K, Plzak LS, Staskin DR, et al. Autologous and synthetic urethral slings for female incontinence. *Urol Clin North Am* 2002;29:597–611.

KEY POINTS: PUBOVAGINAL SLING MATERIALS

- The ideal material for the construction of a PVS is sterile, biocompatible, noncarcinogenic, and consistent in quality.
- The implanted material should be incorporated into the host with minimal tissue reaction and provide long-lasting suburethral support with minimal complications.
- Autologous materials remain the gold standard and are associated with no tissue reaction and negligible urethral perforation. To decrease operative time, hospital stay, and postoperative recovery, other biomaterials are used.
- In addition, tissue-processing techniques for allografts may disrupt the microstructure and affect their strength properties.
- Xenografts have less tensile strength than allograft in situ and have the highest propensity to encapsulate.
- Synthetic materials are characterized by significant inflammatory and foreign body reactions and are associated with higher rates of graft infection and perforation.

important secondary to the increased awareness of patients and their families regarding the **potential dangers of synthetic mesh**. Patients should also be counseled about the risk of **transient and permanent voiding dysfunction after surgery**. This should include a discussion of postoperative difficulty emptying the bladder and de novo urgency and frequency. Of note, teaching patients how to perform CIC preoperatively may decrease trips to the emergency room and the need for an indwelling catheter.

Pubovaginal Sling Anesthesia, Patient Positioning, and Preparation

PVSs may be performed using spinal or general anesthesia, but the choice of anesthesia is typically based on patient, surgeon, and anesthesia provider preference. An AUA Best Practice Policy Statement from 2008 recommends the preoperative administration of a single dose of a first- or second-generation cephalosporin, aztreonam (in cases of renal insufficiency), or an aminoglycoside plus metronidazole or clindamycin (Wolf et al, 2008). We routinely place bilateral lower extremity intermittent pneumatic compression (IPC) devices before administration of anesthesia. The AUA Best

Practice Policy Statement for the Prevention of Deep Venous Thrombosis in Patients Undergoing Urologic Surgery states that for incontinence surgery, the use of IPC devices, low-dose unfractionated heparin, or low-molecular-weight heparin should be based on individual patient and procedural risk factors (Forrest et al, 2008). The patient is placed in the dorsal lithotomy position, and the abdomen (from umbilicus down) and vagina are prepared and draped in sterile fashion. In the United States, povidone-iodine is the most commonly used antiseptic for vaginal preparation; however, in other countries this is not the case (American College of Obstetricians and Gynecologists [ACOG], 2013). In September 2013, ACOG released a committee opinion that chlorhexidine gluconate solutions containing 4% alcohol or less were both safe and effective for vaginal preparation (off-label use).

Next a weighted speculum is placed in the vagina and an 18-Fr Foley catheter is inserted into the urethra. The patient should be placed in moderate Trendelenburg position; for optimal visualization during vaginal dissection, the surgeon may benefit from a headlight. A vaginal ring retractor is used initially for retracting the labia majora and later to retract the incision to further improve visualization and ease of dissection.

In the case of fascia lata harvesting, the IPC device is placed below the patient's patella on the harvest side. The knee is elevated and supported with a 1-L bag of intravenous fluid or an appropriate cushion or pad. The involved extremity is internally rotated at the hip and secured to the table using 3-inch tape, below the operative site. The thigh is prepared and draped to expose its anterolateral aspect from the greater trochanter to the patella distally. The greater trochanter and lateral femoral condyle of the femur are identified and marked. These landmarks denote the proximal and distal attachments of the fascia lata (Dwyer and Kreder, 2008).

Graft Harvest for Autologous Pubovaginal Sling

A 6- to 7-cm Pfannenstiel incision is made approximately 2 cm above the pubic symphysis and carried down to the rectus fascia. A 2-cm × 8-cm graft is then marked out on the rectus fascia in a transverse or longitudinal direction. The premarked graft is harvested out of the rectus fascia using a scalpel or electrocautery (Fig. 84-1A). If a transverse fascial incision is used, maintaining a 2-cm or greater distance away from the pubic symphysis will help ensure a tension-free fascial closure. Freeing the edges of the fascia away from the underlying rectus muscle with a scalpel or electrocautery may also aid in a tension-free closure but could theoretically weaken the fascia. The fascia is closed with a running No. 1 polydioxanone

Figure 84-1. A, Rectus fascial graft harvest. B, Autologous fascia lata harvest.

(PDS) or similar suture. If the fascia cannot be closed adequately, it may be necessary to place an interposing segment of synthetic mesh or biologic graft.

After harvest, the autologous graft is placed in a 0.9% normal saline solution. On a sterile side table, the overlying fat and per fascial tissue are cleaned off of the graft and a separate No. 1 PDS or 1-0 polypropylene suture is secured to each end of the graft. Each suture should be placed perpendicular to the sling fibers (transverse harvest only), run across each end of the graft, and tied down. Sutures are left long, and the graft is again placed in the 0.9% normal saline until needed.

For fascia lata harvest, a 3-cm longitudinal incision is marked beginning just above the patella over the iliotibial band (Fig. 84-1B). Dissection is carried down to the level of the fascia lata, where two parallel, longitudinal, incisions 2 cm apart are made. The graft is bluntly lifted off the underlying muscle and clamped as far distally as possible with a right-angle clamp (3 to 4 cm) and transected, allowing one free end. The free end is secured with a No. 1 PDS suture, and the proximal fascia lata is lifted off the muscle belly with a thin, malleable retractor. The fascia lata is separated from both the adipose tissue and muscle fibers by passing the retractor superficial and deep to the fascia lata. With the free distal end under tension, a Crawford fascial stripper is used to extend the fascial incision proximally and divide it before removal. Classically, the fascial strip was 20 × 2 cm in dimension; however, now shorter lengths (8 cm) are used (Karram and Bhatia, 1990). Another No. 1 PDS suture is secured to the other free end of the graft and the sling is placed in 0.9% normal saline until needed. Immediate compression is applied to the thigh to constrict perforating vessels. The area is carefully evaluated for arterial bleeders before closure. The wound is irrigated and closed in three layers without closing the fascia lata. Once the thigh closure is complete, a compressive wrap is applied to the thigh, and the IPC device is replaced. The compressive bandage should remain in place for 8 hours postoperatively, and early ambulation should be encouraged (Dwyer and Kreder, 2008).

Pubovaginal Sling Vaginal Approach

Initially, 0.9% sterile normal saline is injected into the vaginal epithelium, surrounding the urethra to provide hydrodistention and aid in tissue dissection. We prefer an inverted U-shaped incision because it provides excellent exposure of the urethra to the level of the bladder neck and direct access to the endopelvic fascia and subsequently retropubic space (Fig. 84-2). The top of the incision is made approximately 2 cm below the urethral meatus (an Allis clamp placed immediately below the meatus improves visualization), and the arms of the U should extend to the level of the bladder neck (determined by palpation of the Foley balloon). A

15-blade knife is used to carry this incision down through the vaginal epithelium, with care to stay above the periurethral and pubocervical fascia (to avoid bleeding and injury to the urethra and bladder). With an Allis clamp and Metzenbaum scissors, thick vaginal epithelial flaps are created. The flaps are retracted with help of the vaginal ring retractor.

Once adequate lateral flaps have been created, the ischiopubic rami should be easily palpable, and it is now appropriate to perforate the endopelvic fascia. To prevent inadvertent bladder perforation, it is imperative that the bladder be adequately drained before this maneuver and before the later passage of Stamey needles or larger clamps. With the Metzenbaum scissors angled toward the ipsilateral shoulder and the tips pointed upward, the endopelvic fascia is perforated by remaining directly medial and immediately under the ischiopubic ramus at the superior margin of dissection (Fig. 84-3). Perforation occurs in a superolateral direction, and the Metzenbaum scissors are spread widely to aid in the next step of dissection. Using blunt finger dissection, the retropubic space is dissected bilaterally (Fig. 84-4). With this dissection, the infrapubic and retropubic dissection planes are now connected. During this step, it is important to ensure that the retropubic space is fully opened. The posterior surface of the pubic symphysis should be easily palpable with very little intervening tissue. Intraoperatively, this allows for free movement of the sling and easy tensioning.

Figure 84-3. Perforation of endopelvic fascia.

Figure 84-2. Inverted-U incision.

Figure 84-4. Blunt dissection of retropubic space.

Figure 84-5. Passage of Stamey needles behind pubis.

Even though the abdominal fascia is closed, simultaneous finger palpation through the abdominal and vaginal incisions should be possible, while gently palpating the bladder medially. Aggressive medial mobilization should not be attempted because it may result in bladder injury. Hemostasis should be achieved with bipolar cautery. In the case of women who have undergone prior urethral suspension or sling procedures, more aggressive sharp dissection may be required. In difficult cases, the safest dissection plane into the retropubic space should be immediately adjacent to the periosteum of the pubis, and dissection should be performed sharply as much as possible to minimize the risk of injury to the pelvic viscera.

Pubovaginal Sling Placement and Fixation

Stamey needles are passed from above, through the abdominal incision by careful guidance behind the pubis. The needles are in contact with the pubis until they are brought out lateral to the bladder into the vaginal incision (Fig. 84-5). Alternatively, large surgical instruments such as tonsil clamps may also be used instead of the Stamey needles (McGuire and Lytton, 1978; Blaivas and Olsson, 1988). Again it is important to emphasize that the bladder must be completely drained before passage of the Stamey needles to avoid inadvertent bladder injury. Cystoscopy should be performed with a 70-degree lens after passage of needles to confirm integrity of the bladder, by following the course of needles (while an assistant moves the needles downward and medially toward the bladder). Except when there is hematuria visible or other cause for suspicion, all urologists do not perform cystoscopy after needle passage (Niknejad et al, 2002; Seung-June et al, 2007). It is our belief that cystoscopy is an essential step that eliminates the serious complication of sling perforation of the bladder. In the case of a small bladder injury or inadvertent passage of Stamey needles through the bladder, the needles are removed and passed again and the procedure is completed. Once extravasical passage is confirmed, the Foley catheter is replaced and an ampule of indigo carmine is given to confirm ureteral efflux during final cystoscopy for sling tensioning.

The ends of graft suture are passed through the Stamey needle eyelets. After marking the center of the graft with a clamp, the Stamey needles are removed and the ends of the suture are brought out through the abdominal incision and tagged with hemostat clamps (Fig. 84-6). The distal aspect of the graft is sutured to the periurethral tissue with two simple 4-0 polyglactin 910 sutures. After adequate hemostasis is achieved, the vaginal incision is closed with a watertight, running 2-0 polyglactin 910 suture. Before final tensioning of the sling, the vagina should be closed and weighted speculum removed to eliminate distortion that can affect the final tension. In addition, any additional procedures, such as transvaginal pelvic prolapse repair, should be completed before sling tensioning. The PDS sutures are tied down above the rectus

Figure 84-6. Sagittal view of pubovaginal sling position at bladder neck in retropubic position.

Figure 84-7. Passage of and tying of sling through abdominal incision.

fascia (Fig. 84-7) while cystoscopy with a 30-degree lens is performed to visualize adequate coaptation of the proximal urethra. In most cases the sling should be tensioned with a two-fingerbreadth width distance between the rectus fascia and the PDS knot. The amount of tension may vary owing to the mobility of the urethra or desire to create permanent retention in an individual who will do permanent catheterization. The abdominal incision is closed with a subcuticular 4-0 polyglactin 910 suture. The Foley catheter is left to straight drainage and a conjugated estrogen-covered vaginal packing is placed.

Pubovaginal Sling Postoperative Care

The vaginal packing is removed on postoperative day 1 and the Foley is removed once the patient is out of bed and ambulating (postoperative day 1). If the patient voids adequately (on PVR confirmation), she is discharged home. If she is unable to urinate or has an elevated PVR volume, she is discharged home with a Foley catheter. She will return within 5 days for a repeat trial of void. Patients are instructed to avoid heavy lifting (more than 5 pounds) and sexual intercourse for 6 weeks after surgery. Sexual intercourse should be resumed only after a physical examination and confirmation by the surgeon, but no sooner than 6 weeks after surgery.

KEY POINTS: PUBOVAGINAL SLING OPERATIVE PROCEDURE

- Closure of the rectus fascia without tension is sometimes problematic. To prevent this difficulty, it is important to maintain a distance of 2 cm or more from the pubic symphysis.
- If undermining the fascial edges does not adequately mobilize the fascia, then interposition of a segment of synthetic mesh or graft may be necessary.
- It is important to ensure that the bladder is empty before dissection in the retropubic space or passage of needles.
- It is recommended to perform a cystoscopy after trocar passage to ensure integrity of the bladder and at the time of sling tensioning to visualize the bladder neck.

Outcomes of Pubovaginal Slings for Predominantly Stress Urinary Incontinence

Autologous Pubovaginal Slings

Since McGuire's reintroduction of the autologous PVS in 1978 with an 80% overall success rate (McGuire and Lytton, 1978), even with long-term follow-up continence rates have been reproducibly satisfactory after this surgery (Table 84-3). The earliest series (McGuire et al, 1987; Blaivas and Jacobs, 1991) with rectus fascial slings included a diverse and complex patient population: pelvic radiation, diabetes, spinal cord injury, and pelvic trauma. In the McGuire study, even the 34% of patients with "proximal urethral function loss" documented by urodynamics (MUCP <4 cm H₂O per the article) had a high 82% cure rate (McGuire et al, 1987). In addition, the majority of the patients who required CIC postoperatively had a neurogenic bladder and were counseled to expect urinary retention.

In a retrospective study of 63 women with ISD from 1996, Mason and Roach (1996) confirmed the success of a smaller (4 × 2 cm) modified rectus fascial sling with an average 12-month follow-up. Postoperatively, 12 (19%) patients had urgency and 10 (15.9%) had frank urge urinary incontinence (UUI). However, by 6 months these symptoms had resolved in all but 3 (4.8%), who remained on anticholinergic medication.

Cross and colleagues (1997) found that in patients with grade 3 or 4 cystoceles and SUI, an anterior colporrhaphy in conjunction with a PVS yielded excellent results. In their study, 33 (92%) of the cystoceles were cured on physical examination a median 20.4 months after surgery. Thirty-two patients (89%) were cured of their urinary incontinence based on the results of a urinary system questionnaire. However, they also reported a 19% rate of postoperative de novo urgency and urgency incontinence. Yet only 3% had persistent urgency incontinence requiring treatment. Lastly, 2.8% underwent further urethrolisis to resolve voiding difficulties related to obstruction.

One year later, the same authors published their results of a retrospective analysis of 150 patients who underwent PVS for urinary incontinence (Cross et al, 1998b). In that study, 98% of the patients had predominantly SUI and 93% of all patients were cured of their incontinence based on the results of in-office questionnaires and telephone interviews. Also in 1998, Chaikin and colleagues presented the results of a retrospective analysis of 251 women who underwent autologous PVS procedures. The authors reported an overall 92% cured or improved rate. It is interesting to note that in that study the authors also compared the correlation of different methods of assessing outcomes after surgery. The authors found that there was excellent agreement among a validated questionnaire, pad test, voiding diary, and subjective physician assessment (kappa coefficient greater than 0.9).

Hassouna and Ghoniem (1999) reported long-term outcomes of a modified rectus fascial pubovaginal sling (MPVS) in 112

patients with an 89% rate of primarily SUI symptoms. Ghoniem first described the MPVS in 1991 as a modification of the free rectus fascial strip technique popularized by McGuire. The MPVS involves the fixation of a 7- × 2.5-cm graft to the pubocervical and periurethral ligaments in a four-quadrant manner. In 1991, Ghoniem reported a 95% success rate; however, the more recent study by Hassouna and Ghoniem (1999) assessed outcomes using a quality-of-life (QoL) questionnaire and found a lower 80.8% rate of success. In this later study, all 15 of the patients with documented failure had urgency incontinence or severe irritative symptoms. The additional QoL assessment highlights the impact that urgency incontinence, frequency, nocturia, and pain can have on patient satisfaction.

In 2000, Morgan and colleagues published the results of a retrospective study of 247 women who underwent a PVS procedure with a long mean follow-up of 51 months. In this study, 56% of patients had genuine SUI symptoms, and outcomes focused on QoL were measured using the Urogenital Distress Inventory (UDI) short form. The authors reported an 85% cure rate at 5 years; however, for this level of cure to be achieved, 14 patients (5.7%) had secondary procedures. This included 6 periurethral collagen injections and 3 repeat PVSs. In addition, 5 patients had obstructive symptoms that required urethrolisis. Four of these 5 women had a subsequent return to normal voiding. Important to note, this study shows that when stress incontinence has resolved for more than 1 year after an autologous PVS, the long-term risk of recurrent stress incontinence is low.

A 2001 study by Groutz and colleagues of 67 patients is noteworthy because it reported outcomes based on whether the PVS was for primary (57%) or recurrent incontinence (43%). The latter group had undergone one to three prior unsuccessful anti-incontinence procedures for recurrent incontinence. In terms of the prior procedures, the rates of needle suspension, retropubic suspension, and PVS were 31%, 28%, and 10%, respectively. The cure rate was significantly higher in patients with primary incontinence than in those with recurrent incontinence (74% vs. 59%, $P = .006$). Yet there were no surgical failures in either group. All of the patients were either cured or improved based on their outcome scores that incorporated 24-hour voiding diary, 24-hour pad test, and patient satisfaction.

In a retrospective review and telephone interview of 57 patients who had undergone a PVS procedure for incontinence, Richter and colleagues (2001) assessed long-term QoL. Like the study by Groutz and colleagues, this study also included a significant number of patients who were treated with a PVS for recurrent incontinence after a previous retropubic suspension (46%) or needle suspension (24%). Also, with a rate of postoperative voiding dysfunction comparable to that of patients undergoing their first anti-incontinence surgery, this study again showed that a PVS is effective treatment for recurrent SUI. Overall, telephone interviews that focused on QoL revealed that 88% of patients felt the sling improved their QoL, and 82% stated that they would undergo the surgery again. Remarkably, in 87% of patients, the initial postoperative voiding trial failed, and 11.8% required long-term CIC. The telephone interviews revealed that 5.8% of the patients had to use adaptive positions to facilitate voiding, but, it is interesting to note, all of these patients were satisfied because of freedom from urinary incontinence and did not elect urethrolisis. This satisfaction may relate to an emphasis during preoperative counseling in conveying the possibility of long-term voiding dysfunction after a PVS procedure.

Petrou and Frank (2001) also looked at recurrent urinary incontinence but focused on the safety and efficacy of a repeat PVS procedure after failed suburethral slings in 14 women (5 cadaveric bone-anchored suburethral slings, 3 autologous PVSs, 3 cadaveric bone-anchored PVSs, and 3 vaginal patch slings). Overall, 86% of the patients considered themselves cured or improved after surgery. Postoperative complications included a pelvic abscess related to a prior cadaveric sling, osteomyelitis pubis related to the prior bone-anchored sling, and 1 case of long-term urinary retention.

A 2006 study by Howden and colleagues is worth discussing because of its long 7.1-year mean follow-up and relatively large

153-patient sample size. The authors retrospectively assessed outcomes using four different validated questionnaires and found that 71.7% of patients were continent and only 3.3% required reoperation because of SUI.

The Stress Incontinence Surgical Treatment Efficacy Trial (SISTER) (Albo et al, 2007), a multicenter, randomized clinical trial, compared the rectus fascial autologous sling (326 women) with Burch colposuspension (329 women). The two primary outcomes were composite measures of success in terms of overall urinary incontinence (no self-reported symptoms of incontinence, increase of <15 g in pad weight during a 24-hour pad test, and no medical or surgical treatment for incontinence) and in terms of stress incontinence (no self-reported symptoms of stress incontinence and negative stress test result). The authors found that whereas the PVS was more effective at curing SUI (47% vs. 38%, $P < .001$), it was associated with a significantly higher rate of postoperative voiding dysfunction and cystitis. Of note, all of the surgical procedures for bladder outlet obstruction (20) occurred in the sling group, and 2 patients in the Burch colposuspension group experienced ureteral injuries.

A 2011 study by Athanasopoulos and colleagues was one of the earliest and largest studies to describe the outcomes of the PVS in patients in whom treatment with a MUS had failed. In this study of 264 patients, 29.9% had a prior history of MUS and all of the patients underwent partial sling removal at the time of PVS placement. The authors reported an overall success rate in terms of markedly improved or cured incontinence of 84.7%, and a history of previous incontinence surgery did not affect this outcome.

The study with one of the longest follow-up periods after PVS sling surgery in the literature is a 2013 retrospective study by Lee and colleagues (2015) of 84 patients with a median follow-up of 89 months. The overall improved or cured rate measured by validated questionnaires was 63%. The authors focused their analysis on comparing patients with previous incontinence surgery versus patients undergoing what they called primary PVS surgery and, similar to earlier studies, found no difference in outcomes. Of note, in their first table the authors reported that they included the 4 patients with a prior history of MUS in the primary PVS group, but this appears to be an error.

Rectus fascia is the most commonly used autologous material. However, intermediate and long-term results of fascia lata PVSs are comparable to those of rectus fascia (Beck et al, 1988; Govier et al, 1997). In a retrospective study of 170 patients with recurrent stress incontinence, Beck and colleagues (1988) noted an impressive 92.4% cure rate measured by absence of leakage on a postoperative cough test (full bladder, standing and sitting). It is interesting to note that the authors tested intraoperative urethral pressure to ensure that the slings could create pressures of 80 to 90 cm H₂O. A 1997 study by Govier and colleagues using fascia lata grafts is particularly noteworthy because the authors compared outcomes of a chart review with responses to a questionnaire and found that the latter yielded worse but likely more accurate outcomes (87.5% vs. 70%, respectively). This patient satisfaction–derived cure rate was similar to the questionnaire-based outcomes noted by Brown and Govier (2000). In addition, in this study, all of the patients had thigh pain at 1 to 2 weeks, and 11% described persistent thigh pain at 6 weeks. Latini and colleagues (2004) used the Crawford fascial stripper to obtain fascia lata. They also reported that 1-week postoperatively, 20% of patients had localized numbness at the harvest site, 7% had harvest site pain, and 5% had tendinitis in harvest site leg. Despite this, 83% of respondents indicated that the procedure had had a positive effect on their life, 82% would recommend the surgery to a friend, and 83% would undergo the procedure again.

In summary, over the past 15 years the continence rate after PVS has ranged from 61% to 97%, although the measurement of outcomes is varied. In general, there is no direct correlation between universally accepted objective and subjective measures of improvement or cure for anti-incontinence procedures (Padmanabhan and Nitti, 2006). The most commonly cited reason for failure relates to urgency symptoms, and urgency incontinence at follow-up

is a common reason for patient dissatisfaction. Postoperative de novo or urgency incontinence rates range from 2% to 20.8% (Mason and Roach, 1996; Zaragoza, 1996; Haab et al, 1997; Chaikin et al, 1998; Cross et al, 1998b; Hassouna and Ghoniem, 1999; Morgan et al, 2000; Groutz et al, 2001; Flynn and Yap, 2002; Albo et al, 2007; Mitsui et al, 2007; Onur et al, 2008).

Allograft Pubovaginal Slings

The autologous fascial PVS remains the gold standard treatment for SUI with efficacious and durable outcomes. However, in an effort to reduce overall morbidity, operative time, and pain related to graft procurement, cadaveric allograft slings were introduced (Table 84-4). In general, there are limited outcome data, and the efficacy and durability of these slings are questionable. Early literature used cadaveric frozen or freeze-dried fascia lata with a variety of methods to secure the sling, such as suture fixation and bone anchors (Handa et al, 1996; Wright et al, 1998; Fitzgerald and colleagues, 1999; Amundsen et al, 2000b; Brown and Govier, 2000; Carbone et al, 2001; Flynn and Yap, 2002; O'Reilly and Govier, 2002; Walsh et al, 2002; Richter et al, 2003; Almeida et al, 2004; Howden et al, 2006). Experience has shown that these tissue-processing techniques can have deleterious effects on cadaveric sling outcomes (Nazemi et al, 2008). Failure rates for frozen or freeze-dried grafts range from 6% to 37.6% (Handa et al, 1996; Wright et al, 1998; Fitzgerald et al, 1999; Brown and Govier, 2000; Carbone et al, 2001; Flynn and Yap, 2002; O'Reilly and Govier, 2002; Walsh et al, 2002; Amundsen et al, 2003; Richter et al, 2003; Almeida et al, 2004; Howden et al, 2006).

Handa and colleagues (1996) reported on some of the earliest short-term outcomes for cadaveric fresh-frozen and freeze-dried fascia lata, with promising cure rates. Two of their patients (12%) developed abdominal wound infections, which resolved with local care, including drainage. They reported de novo urgency in 36% of the patients. Two of the 3 patients who had stress incontinence recurrence were continent after undergoing a synthetic MUS procedure.

Fitzgerald and colleagues (1999) reported on 35 patients undergoing cadaveric irradiated fascia lata sling placement with a high failure rate of 17%. Symptom recurrence was seen very early (1 week to 5 months). Histopathologic analyses of the retrieved material indicated the following ongoing processes in the failed graft: disorganized remodeling, areas of graft degeneration, and evidence of immune reaction. These findings led the researchers to conclude that freeze-dried, irradiated donor fascia lata grafts should not be used for urogynecologic procedures owing to the high material failure rate.

Two studies of patients with predominantly SUI symptoms (Walsh et al, 2002; Richter et al, 2003) documented good results without significant adverse outcomes using freeze-dried fascia lata. Walsh and colleagues (2002) prospectively evaluated 31 women with promising short-term follow-up. There was complete resolution of SUI in 94% at both 4 months and 1 year. There was also an improvement in the presence and severity of urgency and urgency incontinence after surgery, reflected in the declining use of anticholinergic medications from before surgery to 4 months and 1 year postoperatively (55% to 32% to 26%). Richter and colleagues (2003) conducted a prospective long-term study using validated questionnaires for a follow-up of 48 months. Difficulty emptying the bladder was described by 58.2% of patients at 12-month follow-up, with 34.2% describing it as slight. By 48 months, 50% of patients continued to have difficulty emptying their bladders. Patients reported a 90.2% satisfaction rate at 12 months' follow-up and continued to be satisfied at 48 months' follow-up (85.7%).

Two groups documented high failure rates with freeze-dried allograft (Carbone et al, 2001; O'Reilly and Govier, 2002). Carbone and colleagues (2001) used cadaveric fascia with titanium bone anchors for placement bilaterally in the pubic symphysis. They reported a 38% failure rate and 17% reoperation rate, at a short-term follow-up of 11 months. Average time to reoperation was 9 months (3 to 15 months). Intraoperative findings at reoperation

revealed the titanium anchors to be in position, the polypropylene sutures to be intact, and retropubic fibrosis and scarring of the urethropelvic ligament suggesting appropriate placement of the sling. However, all of the allogenic fascia appeared to be fragmented, attenuated, or simply absent. These authors have subsequently abandoned the use of cadaveric fascia allografts in all PVSs at their institution. O'Reilly and Govier (2002) reported high intermediate failure rates in 121 women. Eight patients had recurrent stress incontinence at a mean of 6.5 months (4 to 13 months). Seven of the 8 women had previous incontinence surgery and had multiple comorbidities including neurologic disease, diabetes, previous pelvic irradiation, and previous pelvic surgery. Based on these results and findings by Lemer and colleagues (1999), this group also discontinued the use of fresh-frozen grafts and switched to solvent-dehydrated cadaveric fascia and dermal grafts.

Huang and colleagues (2001) were the earliest group to report unfavorable experiences using solvent-dehydrated allografts in 18 women with short-term follow-up. They reported a 27.8% failure rate with full recurrence of incontinence and subsequently stopped using all allograft as a sling material. On reoperation with an autologous PVS for recurrent SUI, the allograft remained only rudimentary and was very friable. Histologic examination of the retrieved allograft revealed wavy collagen fibers with loosely packed fibroblasts and focal areas of degeneration.

In 2005, Frederick and Leach reported prospective, intermediate-term results of a surgery that used a solvent-dehydrated cadaveric prolapse repair and sling (CaPS) anchored to the pubic symphysis to correct both anterior compartment prolapse and incontinence, with cured, improved, and failure rates of 56%, 26%, and 17.5%, respectively. There was one case of osteitis pubis related to use of transvaginal bone anchors that resolved with conservative management. It is interesting to note that 56% of the failures occurred after 12 months of follow-up. Overall, 80% of the women were satisfied and 77% stated that they would undergo the CaPS procedure again. In another study using validated questionnaires (i.e., UDI-6, Incontinence Impact Questionnaire [IIQ-7]) after cadaveric fascia lata PVS surgeries, Pianezza and colleagues (2007) reported on similar levels of long-term patient satisfaction. They found that patients with preoperative mixed incontinence were at the greatest risk

for postoperative dissatisfaction. Nazemi and colleagues (2008) described durable improvements in incontinence episodes, patient satisfaction, and validated QoL end points in both a CaPS and a CaTS (cadaveric transvaginal sling placement alone) cohort. Yet there was a reduction in dry rates with extended follow-up (24 months, 48 months, and 60 months), especially in the CaTS group (23%, 18%, and 9%, respectively). Lastly, 4% of patients developed sling extrusion, and 4% required sling incision and urethrolisis.

Because of early and intermediate graft failure with cadaveric fascia lata, surgeons were impelled to use alternative materials such as cadaveric dermal grafts. Crivellaro and colleagues (2004) presented their prospective series of patients treated with bone-anchored Repliform cadaveric human dermal allograft (LifeCell, The Woodlands, TX) PVS. There was a 22% failure rate, and average incontinence improvement rate at 9 months was 85% and at 18 months was 80%. The two patients requiring long-term intermittent catheterization had neurogenic bladders. Owens and Winters (2004) assessed outcome and patient satisfaction with Duraderm allograft (C.R. Bard). Initial results were promising with a dry rate of 68% and improved rate of 24%. At intermediate follow-up, only 32% of the patients were dry and 36% noted improvement. Two of the eight patients experiencing failure underwent periurethral bulking agent injections with significant improvement, and one is dry after an autologous sling procedure. Surgical re-exploration revealed almost complete absence of graft material, without evidence of infection or excessive inflammatory response.

Six studies have compared the outcomes of women undergoing PVS procedures using either autologous or cadaveric allograft fascia (Wright et al, 1998; Brown and Govier, 2000; Flynn and Yap, 2002; Almeida et al, 2004; Howden et al, 2006; Onur et al, 2008). Four groups found the outcomes comparable with equally high success rates and no negligible difference in complications. They concluded that allograft fascia lata may be used as an alternative to autologous fascia for PVS, to reduce operative time and decrease postoperative pain and disability (Wright et al, 1998; Brown and Govier, 2000; Flynn and Yap, 2002; Onur et al, 2008). With long-term follow-up, two groups noted superior continence outcomes in the autologous group (Almeida et al, 2004; Howden et al, 2006). Almeida and colleagues (2004) did not report adverse outcomes in either group.

TABLE 84-5 Outcomes with Xenograft Pubovaginal Slings

Wilson et al, 2008	37	Xenform Matrix*	67.7	NR	19.5	83.8% SUI cured 54.1 global cured	Stress test; VQ	NR	NR

*Xenform Matrix is an acellular bovine dermis.

CR, chart review; GSI, genuine stress urinary incontinence; NR, not recorded; SIS, single-incision sling; SUI, stress urinary incontinence; VQ, validated questionnaire.

Howden and colleagues (2006) found that recurrent symptoms occurred in a higher proportion in the cadaveric group (39.6%) compared with the autologous group (28.3%) ($P = .04$). The reoperation rate was also higher for the allograft group (12.7% vs. 3.3%, $P = .003$).

Some studies support the efficacy of solvent-dehydrated fascial slings (Frederick and Leach, 2005; Onur and Singla, 2005; Pianezza et al, 2007; Nazemi et al, 2008), yet previously reported failures coupled with the consistent success and rapid adoption of synthetic MUSs has led to abandonment of all types of cadaveric allograft at most centers. Thus there is a paucity of data to assess long-term outcomes and define sling outcomes after solvent-dehydration techniques (Nazemi et al, 2008).

Synthetic Material Pubovaginal Slings

There are few randomized studies looking at outcomes after placement of a synthetic PVS. One of those studies is a prospective randomized trial comparing the synthetic PVS procedure with the Burch colposuspension (Sand et al, 2000). In this study 17 women were randomized to receive the sling. The authors concluded that the synthetic suburethral sling placed at the bladder neck under tension had equivalent results to the modified Burch procedure after a short 3 months of follow-up. The sling material used was ePTFE. It is interesting to note that although the authors reported no problems with exposure or perforation, they state in their discussion section that they stopped using this type of sling because of complications reported by Weinberger and Ostergard (1995).

In that study by Weinberger and Ostergard (1995), 108 women were treated with an ePTFE PVS for SUI; 40% developed a wound complication and 21% required complete or partial sling removal (10 with sinus tract formation, 4 with persistent vaginal granulation, 3 with prosthetic exposure, and 1 with groin pain). Clearly because of its material properties (small pores), ePTFE is not an ideal synthetic sling material. Likewise, there have also been problems with other synthetic sling materials (polyethylene and polypropylene) with less-than-ideal physical properties placed under tension at the bladder neck (Drutz et al, 1990; Young et al, 2001; Wohlrab et al, 2009).

Xenograft Pubovaginal Slings

Because of the morbidity of autologous fascial harvest, high failure rates of allograft materials, and high exposure and perforation rates

with synthetic PVSs, xenografts are an attractive option. In general, they are associated with a low rate of infection, exposure, and perforation owing to their incorporation into host tissue (Rutner et al, 2003). The majority of studies in the literature have used gamma-sterilized porcine dermis (Pelvicol, C.R. Bard), porcine SIS, and bovine dermis as xenografts for use in PVSs (Arunkalaivanan and Barrington, 2003; Rutner et al, 2003; Abdel-Fattah et al, 2004; Wiedemann and Otto, 2004; Giri et al, 2006; Wilson et al, 2008) (Table 84-5).

Rutner and colleagues (2003) were the first to describe the use of porcine SIS as a bone-anchored PVS in 152 patients with long-term follow-up. They reported cure rates comparable to those of the autologous sling. Among the 7 failures (4.6%), 5 patients had recurrent SUI within 3 months of surgery, and the other 2 had recurrences at 9 and 11 months postoperatively. Two of the failures were related to the bone anchors. One patient had repeat porcine SIS PVS, with continued failure to relieve incontinence, and 1 patient became dry after carbon bead periurethral bulking injections. One patient achieved continence with urethrolisis 2 years after the initial surgery. At reoperation, grossly no evidence of the implanted SIS material was found. However, biopsies of the periurethral tissue did reveal fibrosis and muscular tissue with a few remnants of SIS. Wiedemann and Otto (2004) performed the first extensive histopathologic examination of porcine SIS in a series of 15 women with SIS PVSs. Three reoperations (20%) were necessary because of recurrent SUI at a mean of 12.7 months. All 3 patients underwent reoperation with implantation of a polypropylene mesh sling and achieved immediate continence. Biopsy specimens from the SIS band under the vaginal mucosa of those 3 patients revealed only focal residues of SIS without any evidence of tissue reaction. There was also no evidence of a significant immunologic or chronic inflammatory reaction. These authors concluded that the advanced incorporation of the implant would lend to good biocompatibility.

Arunkalaivanan and Barrington (2003) first reported on Pelvicol PVSs in a randomized, short-term trial comparing Pelvicol PVS with TVT. Questionnaire-based cure rates were comparable between the two: 85% in the TVT group and 89% in the Pelvicol implant group. Abdel-Fattah and colleagues (2004) presented the 3-year follow-up data for this prospective trial. Cure rates remained high and comparable between the two groups: 79.1% for the TVT group and 77.8% for the Pelvicol group. There was no statistical difference with regard to complication rates or postoperative pad score. Giri and colleagues (2006) compared the 3-year efficacy of Pelvicol

versus autologous rectus fascia in 101 consecutive, nonrandomized patients. Although porcine dermis reduced the associated surgical morbidity, there were significantly inferior long-term cure rates compared with the autologous PVS. Treatment failure occurred by 9 months in the autologous group and by 24 months with the Pelvicol sling. Repeat urodynamic studies indicated stress incontinence as the cause of treatment failure in 18 of 20 (90%) treated with porcine dermis, but in only 3 of 8 (37.5%) with a rectus fascial sling. These authors concluded that Pelvicol should not be used as a substitute for rectus fascia.

Bovine dermis is the most recently reported material used for a xenograft PVS (Wilson et al, 2008). Women with a high risk for sling failure (advanced age, previous surgical failure, and ISD) underwent either a bovine dermis or autologous rectus fascia PVS procedure with short-term follow-up. Global cure rates and SUI cure rates were not statistically different between the two groups. Four women (8.3%) in the autologous group underwent reoperation with periurethral bulking agent injections, repeat autologous PVS, and anterior colporrhaphy with interposition graft. Two women (5.4%) in the bovine dermis group underwent additional interventions: periurethral bulking agent injections and a repeat autologous PVS. Biopsies of the bovine dermis sling material during reoperation (for SUI recurrence at 3 months) revealed that the sling had been replaced by fibrosis, hemorrhage, and mild chronic inflammatory infiltrate, with no acellular component. Tissue breakdown, represented by intermittent areas of myxoid degeneration, were present and may have indicated evidence of early graft failure.

Outcomes of Autologous Pubovaginal Slings for Mixed Urinary Incontinence

The treatment of patients with mixed urgency and SUI is complicated and often involves a combination of anticholinergic therapy and surgery. Medical therapy for MUI is associated with significant resolution of the urgency component in only two thirds of patients (Nordling et al, 1979; Stephenson and Mundy, 1994). Anticholinergic therapy alone does not address the bladder outlet and would not be expected to achieve complete dryness. However, anti-incontinence surgery may cure or aggravate urgency symptoms or lead to de novo urgency. This aspect of anti-incontinence surgery is unpredictable and a major cause of patient dissatisfaction.

In 1999, Fulford and colleagues were the first group to use video-urodynamics in the assessment of how a PVS affects MUI. In that study, 69% (59 of 85) of the women had MUI. Despite the fact that 97% of all the women were continent, only 66 (78%) were satisfied with the surgical result, because of the persistence of urgency symptoms or de novo urgency in 27 women. Among these 27 women, 41% had an open bladder neck at rest compared with only 8% of the women without postoperative UUI ($P < .01$). The storage symptoms eventually resolved in 69% (32) of the patients, almost all of whom had a closed bladder neck at rest. Of note, the postoperative urgency symptoms were not significantly associated with any preoperative clinical or urodynamic variables.

Schrepferman and colleagues (2000) attempted to predict urinary urgency resolution after a PVS procedure with preoperative video-urodynamics. Sixty-nine women with MUI were divided into two groups: a sensory urgency group (28 women with one or more episodes of subjective symptoms without DO) and a motor urgency group (41 patients with one or more episodes of subjective urgency symptoms correlating with DO). They concluded that there was a significantly greater resolution of urinary urgency symptoms in those with low-pressure DO than in those with high-pressure DO or no DO. Overall, the urgency resolution rate in patients with mixed incontinence was 51%. Also in 2000, Serels and colleagues reviewed the records of 36 patients with stress-induced DO. In that study, 75% of patients had resolution of urgency incontinence and 92% achieved a cure. However, again, ALPPs measured during urodynamic studies did not correlate with outcomes.

Osman (2003) evaluated the outcomes of PVS and Burch colposuspension in patients with MUI (no DO) compared with a control group of patients with genuine SUI. The ALPP on preoperative urodynamic studies was used to determine whether patients underwent a PVS or a Burch colposuspension. The Burch arm consisted of 24 (8 genuine SUI and 16 MUI) patients with an ALPP exceeding 90 cm H₂O, and the PVS arm consisted of 26 (12 genuine SUI and 14 MUI) patients with an ALPP below 90 cm H₂O. In the PVS groups, the incidence of persistent UUI in the MUI patients was 12% and the incidence of de novo UUI in the genuine SUI patients was 20%. The incidence of residual urgency was not significantly higher than that of de novo urgency in those with genuine SUI.

Chou and Flisser (2003) used a validated questionnaire, voiding diary, and pad testing to report the outcomes of PVSs for MUI and genuine SUI. Among 98 patients, 46 (46.9%) had genuine SUI and 52 (53.1%) had MUI (26% with DO). The cure or improvement rates were 97% in the SUI group and 93% in the MUI group ($P = .33$). Increasing episodes of urgency and urgency incontinence on preoperative voiding diary correlated directly with surgical failure, whereas voiding frequency was associated with cure. The authors postulated that these patients might have adopted this frequent voiding preoperatively to avoid incontinence.

Stoffel and colleagues (2008) found no difference in preoperative video-urodynamics between women with MUI and DO and those without DO. However, MUI patients with DO had less improvement in UDI-6 scores than MUI patients without DO, despite similar reduction in pad use. The authors concluded that the presence of preoperative DO on urodynamic findings may relate to decreased QoL and decreased urgency resolution rates after a PVS procedure.

There are to date no consistent video-urodynamic parameters in patients with MUI that relate to outcomes with a PVS. However, the presence of residual urgency is similar to de novo urgency with a PVS. Also, increasing episodes of urgency and urgency incontinence may correlate with surgical failure. Overall, the PVS remains an effective treatment option for MUI with cure rates similar to those of simple SUI.

Outcomes of Autologous Pubovaginal Slings for Urethral Reconstruction

Autologous PVSs serve an important role in the reconstruction of the urethra after anatomic damage (tissue loss) ranging from the relatively mild deformity of urethrocuteaneous fistulae and urethral diverticula to the more severe, traumatic absence of the urethra or bladder neck. The causes of damage also include protracted obstetric deliveries, anti-incontinence surgeries, aggressive transurethral resections of the bladder neck, long-term indwelling urethral catheters, pelvic trauma, tumors, and radiation (Blaivas and Jacobs, 1991). The goals of surgical repair are to restore function and anatomy while fashioning an unobstructed, continent urethra (Blaivas and Heritz, 1996).

Swierzewski and McGuire (1993) reviewed the records of 14 women who underwent urethral diverticulectomy during a 3-year period. Eight patients (57%) had symptoms of SUI preoperatively, and 7 of these women had SUI documented on preoperative urodynamic studies. Only these 7 women underwent a combined urethral diverticulectomy and autologous PVS procedure. All 14 women were cured of their SUI with a mean follow-up of 17 months (3 to 21 months). The authors concluded that the presence of a urethral diverticulum does not compromise the successful cure of SUI by a PVS.

Chancellor and colleagues (1994) performed PVS procedures in 14 women with destroyed urethras secondary to long-term indwelling Foley catheter management of neurogenic bladder dysfunction. In these patients significant tension was applied to the sling suspension to achieve urethral closure. Ten patients had simultaneous intestinal augmentations or diversions and 2 had concurrent suprapubic tube placement. The other 2 had adequate preoperative bladder capacity and compliance. All of the patients achieved

continence after a mean follow-up of 24 months. The authors concluded that the PVS is simpler and avoids the risk of fistula formation associated with bladder neck closure, which has historically been used in the aforementioned patient population.

Blaivas and Heritz (1996) performed a retrospective study of 49 women who underwent a one-stage urethral reconstruction to repair extensive damage to the urethra or bladder neck (45% from prior urethral diverticulectomy) with 4 years' average follow-up. Forty-one of these women had a concomitant PVS placed for management of preoperative SUI. After PVS placement, none of the patients had postoperative SUI and only 1 patient experienced obstruction and urgency symptoms requiring incision and was subsequently continent at last follow-up. On the other hand, 3 of the 5 women who had Pereyra repairs developed postoperative SUI and required secondary PVSs (all 3 were continent at last follow-up). **This study illustrates the fact that the PVS in the setting of urethral reconstruction has excellent results when compared with other surgeries for incontinence.**

Faerber (1998) reported on 16 women who had simultaneous PVS and diverticula repairs after urodynamic evaluation. All of the women were either significantly improved (12%) or cured (88%) of incontinence, and only 2 patients developed de novo urgency. The average time for complete bladder emptying was 5 weeks. For the initial 2 weeks, a Foley catheter was left in place for urethral healing.

Rovner and Wein (2003) reported on the circumferential urethral diverticulum repair in nine patients who received either end-to-end urethroplasties or dorsal urethroplasties. Based on preoperative SUI status or evidence of an open bladder neck on preoperative cystography, eight patients were recommended to undergo concurrent PVS placement. All patients had a rectus fascial PVS sling placed, except one who requested a porcine PVS and one who refused to have a PVS. All patients were continent postoperatively, except for the one patient who refused PVS surgery and developed de novo SUI.

Flisser and Blaivas (2003) evaluated the results of 74 women with urethral pathology who required vaginal flap reconstructions. A majority of the women had required reconstruction for a diverticulum or urethral fistula secondary to iatrogenic causes. Fifty-six of these women underwent a concomitant PVS procedure. The authors found that 73% (54) of the women considered themselves cured postoperatively. In addition, in 3 of the 4 patients who had persistent SUI, a modified Pereyra procedure had failed, but these patients were cured at reoperation. One patient was continent after operative revision of PVS for obstruction and significant urgency incontinence.

KEY POINTS: PUBOVAGINAL SLING OUTCOMES

- The autologous PVS is associated with cure rates of 46% to 97% with variable measurements of outcome used. De novo urgency and urgency incontinence rates are also variable.
- There are no risk factors that consistently predict outcomes after a PVS.
- The reported cure rate of PVS surgery for recurrent SUI is excellent. In randomized trials, porcine dermis was associated with significantly inferior long-term cure rates compared with the autologous PVS.
- Treatment of patients with MUI is complicated and involves a combination of anticholinergic therapy and surgery.
- The PVS is an effective treatment option for stress-induced DO with cure rates similar to those of simple PVS. The presence of preoperative DO may relate to decreased QoL and decreased urgency resolution rates after a PVS procedure.
- Autologous PVSs serve an important role for providing continence and robust tissue coverage in urethral reconstruction (urethral fistula, urethral diverticulum, destroyed urethra).

Voiding Dysfunction Secondary to Bladder Outlet Obstruction after Pubovaginal Sling Surgery

The voiding dysfunction that develops from the iatrogenic bladder outlet obstruction by a PVS is often also related to DO and impaired detrusor contractility. The incidence of voiding dysfunction after PVS surgery varies widely in the literature, from 2.5% to 35% (**Foster and McGuire, 1993; Carr and Webster, 1997; Cross et al, 1998b; Chaliha and Stanton, 1999**). The traditional PVS is known to have higher rates of voiding dysfunction than the Burch colposuspension (**Stanton et al, 1983**). In the SISTER trial comparing the autologous rectus fascia PVS and the Burch colposuspension, success rates were higher for women who underwent the sling procedure, but these patients experienced significantly greater voiding dysfunction (63% vs. 47%, $P < .001$), urinary tract infections (UTIs), difficulty voiding, and postoperative urgency incontinence (**Albo et al, 2007**). A meta-analysis by the AUA Stress Urinary Incontinence Clinical Guidelines Panel reported that the incidence of urinary retention more than 4 weeks after PVS placement was 8% and the risk of permanent retention "generally does not exceed 5%" (**Leach et al, 1997**). In a series of 252 women at 4 years' follow-up, **Morgan and colleagues (2000)** reported a prolonged urinary retention rate of only 2.4%.

The presentation of patients with obstruction is variable and the symptoms range from complete urinary retention and urgency incontinence to the less obvious irritative symptoms. Obstruction may also cause recurrent UTIs, prolonged suprapubic pain, and painful voiding, even if emptying is completed. Nitti and colleagues found that 16% of patients who required PVS lysis did not have obstructive symptoms or retention (**Nitti et al, 2002**). Some studies report persistent postoperative urgency incontinence and urgency as more common presenting symptoms (8% to 25%) than frank retention, after PVS surgery (**Cross et al, 1998b**). The risk of iatrogenic obstruction usually relates to technical factors—that is, placement and tension of sutures or sling material. During surgery, if the sling is too loose, there is an inadequately supported bladder neck (proximal urethra) and there is potential for continued SUI. However, if the sling is tied too tightly, there is excessive elevation of the bladder neck toward the pubic bone, causing hypersuspension or overcorrection of the urethrovesical angle and the potential for obstruction.

It has been shown that preoperative voiding dysfunction affects a patient's ability to empty after anti-incontinence surgery. Subclinical preoperative impaired detrusor contractility may manifest symptomatically with a relative obstruction when urethral resistance is increased by anti-incontinence surgery. Dysfunctional voiding or failure of relaxation of the external (striated) urethral sphincter may also affect emptying after surgery (**Fitzgerald and Brubaker, 2001**). Also, a patient who habitually voids by abdominal straining may have difficulty emptying after incontinence surgery. Because of the variability of presenting symptoms after PVS surgery, it is important to ascertain the predominant symptom with a thorough history.

If a patient has postoperative urethral obstruction, physical examination may reveal an abnormal urethral angulation, a fore-shortened nonpliable vagina, or a nonmobile urethra. However, hypersuspension is usually not evident on physical examination. The PVR volume is very important in the evaluation of voiding dysfunction, although no clear cutoff values for obstruction exist (**Siddighi and Karram, 2007**). Cystoscopy is useful to rule out bladder pathology, sling perforation, and a hypersuspended urethra. Video-urodynamics are useful in selected cases at the physician's discretion. **However, the most important criterion for a sling incision or urethrolisis remains the temporal relationship between the symptoms and the surgical procedure.**

There are no well-established risk factors for patients who are likely to experience voiding dysfunction after PVS surgery. However, several studies have investigated multiple factors that may be predictive. In 1996, Weinberger and Ostergard (1996) studied 108 women receiving synthetic PVSs and found that impaired detrusor contractility predicted postoperative urinary retention. Similarly, in 2003, **Miller and colleagues (2003)** noted that women

receiving an allograft PVS who voided with no or minimal detrusor pressure (19%) had a significantly increased risk of postoperative retention. In contrast, no patient with a normal detrusor contraction developed retention postoperatively. However, other researchers have not confirmed this association between impaired detrusor contractility and subsequent voiding dysfunction after PVS surgery (McLennan et al, 1998). Although urodynamic studies are useful in understanding the voiding dynamics of incontinent women, low detrusor pressure and Valsalva voiding preoperatively should not exclude patients from having an anti-incontinence procedure.

Mitsui and colleagues (2007) further analyzed the risk factors for postoperative voiding dysfunction after PVS surgery. The authors found that patients with a PVR greater than 100 mL ($P = .05$) or Qmax less than or equal to 20 mL/sec ($P = .09$) during preoperative urodynamic studies were more likely to require prolonged intermittent self-catheterization. In this group, 28% needed prolonged intermittent self-catheterization (range 4 to 40 months). Lemack and colleagues (2008) examined the preoperative and postoperative urodynamic data for patients enrolled in the SISTEr trial (prospective, randomized clinical trial comparing PVS with Burch) to predict voiding dysfunction after surgery. Urodynamic findings did not predict postoperative voiding dysfunction or the risk of surgical revision in the pubovaginal group. In general, although postoperative urgency and urgency incontinence (voiding dysfunction) are strongly related to failure, there are no preoperative risk factors that consistently predict these outcomes after PVS surgery.

A key factor in assessing voiding dysfunction is the presence of prolapse that was either uncorrected at time of surgery or that occurred postoperatively. Prolapse of sufficient size may kink or angulate and externally compress the urethra. After surgery, apical, anterior, and posterior prolapse must be ruled out as a cause of the urethral obstruction. In 2000, Kobashi and colleagues reported on a technique of combined cystocele repair and PVS using a single piece of cadaveric fascia. After an average 12.4 months of follow-up, only 1 patient of 132 developed persistent obstruction that required urethrolisis (Kobashi et al, 2002). In 2002, Barnes and colleagues reported on 38 women with grade 3 or 4 pelvic prolapse and occult stress incontinence who underwent concurrent PVS with prolapse repair (Barnes et al, 2002). No patient developed permanent urinary retention. Two (5.3%) of the women developed de novo urgency incontinence. Existing urgency incontinence resolved in 45%. They concluded that concurrent surgery had little negative effect on postoperative bladder emptying. In general, there is a paucity of literature on the effects of concurrent PVS and prolapse repair on postoperative emptying and voiding symptoms.

Surgical Management of Voiding Dysfunction after Pubovaginal Sling Surgery

Although transient urinary retention is common, most patients return to spontaneous voiding within the first 10 days (Zaragoza, 1996; Cross et al, 1998b). Obstruction after an autologous PVS procedure usually improves or resolves with time. This is the reason that most physicians historically prefer waiting 3 months before considering surgical intervention after PVS surgery. (It may not be suitable to wait this long after MUS procedures.) **It is appropriate and effective to initially treat persistent voiding dysfunction conservatively.** This includes temporary catheter drainage, CIC, timed voiding, double voiding, biofeedback, pelvic floor muscle training, and anticholinergic therapy.

In the first 6 weeks after autologous PVS surgery, we have had success with loosening the sling in the operating room using spinal or general anesthesia. This is done by first inserting a cystoscope into the bladder and then gently applying caudal pressure to the urethra. **This procedure is not advised with synthetic slings.** Other anecdotal evidence also shows improvement in obstruction with urethral dilation and downward traction after autologous PVS surgery. These results may vary from temporary relief to worsening of the urethral rigidity secondary to periurethral fibrosis (Zimmern et al, 1987; Beck et al, 1988). Transurethral resection or incision of

the bladder neck is likely to fail because the sling is extraluminal and transurethral resection may cause damage to the sphincter, damage to the bladder neck, or periurethral fibrosis, leading to worsened incontinence or even a bladder neck contracture (Ghoniem and Elgamasy, 1995). After 6 weeks or when conservative measures fail, a formal urethrolisis or sling incision is indicated.

Surgical management of bladder outlet obstruction after a PVS procedure traditionally involves complete urethrolisis by a retropubic, transvaginal, or suprimeatal approach, with success rates of 65% to 93% (Foster and McGuire, 1993; Carr and Webster, 1997; Cross et al, 1998a; Goldman et al, 1999; Petrou et al, 1999). Most of these series include patients with obstruction after different anti-incontinence procedures. Only two groups stratified their results specifically for PVSs (Foster and McGuire, 1993; Petrou et al, 1999). Foster and McGuire (1993) reported that transvaginal urethrolisis was successful in 50% of PVS obstructions, which was less than both needle suspensions (75%) and retropubic urethropexy (63%). Their conclusion was that transvaginal lateral dissection is insufficient in relieving the direct suburethral compressive force of the sling. Petrou and colleagues (1999) reported that the suprimeatal approach is superior to the transvaginal approach because the former allows access and division of the lateral wings of the sling. In their series, 8 of 12 patients had successful results. In another series of 12 women, Petrou and Young (2002) reported resolution of obstruction in 10 patients after retropubic urethrolisis. Of note, 2 of the 10 women with resolution of obstruction developed SUI. Carr and Webster (1997) reported complete or significant resolution of symptoms in 86% of patients after retropubic urethrolisis. Overall, recurrent stress incontinence after formal urethrolisis is reported as 0% to 19%. See Table 84-6.

Sling incision has comparable success rates (84% to 100%) and shorter operative time and less morbidity than formal urethrolisis (McLennan and Bent, 1997; Amundsen et al, 2000a; Shenassa et al, 2000; Kusuda, 2001; Nitti et al, 2002; Goldman, 2003; Thiel et al, 2005a). Most series report the results of simply a single incision of the PVS; however, incision of the sling in conjunction with the interposition of autologous graft material between the cut ends of the sling has been proposed to prevent recurrent incontinence. Ghoniem and Elgamasy (1995) were the first to report on the successful use of sling incision and interposition of a free graft of vaginal wall for obstruction. However, others have found that this technique does not live up to this expectation. Shenassa and colleagues (2000) and McLennan and Bent (1997) used vaginal wall interposition in 12 and 4 women, respectively. The success rates were 92% and 100%, but stress incontinence recurred in 25% of patients in each series.

Several authors have reported on successful midline or lateral sling incision without graft interposition. In 2000, Defreitas and Herschorn (2000) had a 94% success rate in 16 women after lateral sling incision, with a 34% rate of recurrent stress incontinence. Lateral incision is beneficial to avoid urethral injury in cases when the sling is identified, but the dissection plane between the urethra and sling is difficult. Amundsen and colleagues (2000a) used midline incision of a PVS in 10 of 32 patients, in whom the sling was easily identified. In the rest, formal urethrolisis with entrance into the retropubic space was performed. The overall success rate was 84%, but the results were not stratified between sling incision and formal urethrolisis. Of note, in 9 of 12 of the obstructing autologous slings in this study, the sling material could not be identified and was replaced by dense fibrosis. Kusuda (2001) reported successful outcomes for 5 patients who underwent lateral sling incision. Nitti and colleagues (2002) reported on 19 women who underwent PVS lysis for obstruction. The success rate was 84% and the recurrent stress incontinence rate was 17%. Two of the 3 women with failure underwent subsequent successful retropubic urethrolisis. This allowed for complete release of all retropubic space scarring that likely contributed to the failure of the suburethral sling release. Goldman (2003) performed simple sling incision in 14 women with iatrogenic urethral obstruction. This included 3 patients with a midurethral polypropylene mesh sling. In this study, 13 of 14 (93%) patients had complete or significant

improvement of voiding dysfunction and 1 (7%) required subsequent urethrolisis. Also, 21% (3 patients) developed recurrent SUI; however, only 1 required treatment (repeat mesh midurethral sling). Long-term results after simple sling incision were reported by Thiel and colleagues (2005a) for 13 women with catheter-dependent urinary retention after PVS surgery. At 5 years' follow-up, patients reported 45% cure and 45% improvement. Also, 7.7% of the women noted recurrent stress incontinence, but chose not to pursue further therapy.

There are no preoperative or urodynamic parameters that consistently predict success or failure of urethrolisis. Foster and McGuire (1993) found that patients with detrusor instability had a higher rate of failure, but later studies contradicted this. Carr and Webster (1997) found that the only parameter predictive of success was no prior urethrolisis. Nitti and Raz (1994) found that as the PVR volume increased, so did the failure; however, others have not confirmed this.

Failure of urethrolisis may be caused by persistent or recurrent obstruction, DO, impaired detrusor contractility, or learned voiding dysfunction. Recurrent obstruction may result from periurethral fibrosis and scarring or intrinsic damage to the urethra that has occurred from the prior urethrolisis surgery. The most common reason for failure is likely insufficient dissection and lysis of the urethra. Scarpero and colleagues (2003) reported on the value of repeat urethrolisis after failed urethrolisis in 24 women. Both transvaginal and retropubic approaches were chosen depending on the clinical situation. Obstruction was cured in 92%, but storage symptoms resolved in only 12%. Even though they were improved, 69% continued to require anticholinergic therapy. SUI recurred in 18% of the women. This supports the use of repeat urethrolisis in the face of initial failure or in cases wherein the aggressiveness of the initial dissection is unknown. In addition, after an aggressive transvaginal urethrolisis, a retropubic urethrolisis may also be considered.

Refractory storage symptoms after urethrolisis can be challenging to treat. OAB symptoms are refractory in more than 50%,

and this affects patient satisfaction and QoL (Starkman et al, 2008a). There are no predictors of this outcome after urethrolisis, yet DO preoperatively may suggest an increased likelihood of refractory OAB. Also, there are no established guidelines for management. In 2007, Starkman and colleagues examined 25 women with urinary urgency incontinence after urogynecologic surgery (19 PVS, 3 retropubic suspension, and 3 transperitoneal vesicovaginal fistula repair; 4 required further urethrolisis) who were subsequently treated with sacral neuromodulation (SNM). The authors found that SNM was effective (80% reported >50% improvement and 6 were continent) and there were no significant differences in response based on age, duration of symptoms, type of surgery, and urodynamic parameters. One year later, Starkman and colleagues (2008b) evaluated the value of SNM in the management of 8 women who had undergone at least one urethrolisis. Six patients had a favorable response during test stimulation and underwent implantation of an implantable pulse generator (IPG). All 6 of these patients were significantly improved. In summary, in addition to anticholinergics, SNM should be considered as an option for de novo or refractory urgency and urgency incontinence after urethrolisis.

Complications of Pubovaginal Slings

Pubovaginal Sling Perforation and Exposure

The incidence of PVS perforation and exposure is partially dependent on the composition of sling material. Synthetic slings perforate 15 times more often into the urethra and are exposed 14 times more often in the vagina than autologous, allograft, and xenograft slings (Blaivas and Sandhu, 2004). This is based on a meta-analysis of peer-reviewed literature in 1997 (287 articles) (Leach et al, 1997). In this study the urethral perforation rate was 0.02% and the vaginal exposure rate was 0.007% in 1515 patients who received synthetic slings. This is compared with a urethral perforation incidence of 0.003% and a vaginal exposure incidence of 0.0001% in 1715 patients undergoing autologous and allograft

KEY POINTS: VOIDING DYSFUNCTION AFTER PUBOVAGINAL SLING

- Obstruction, DO, and impaired detrusor contractility are manifestations of voiding dysfunction from iatrogenic outlet obstruction by a PVS.
- The incidence of permanent retention is usually 5% or less.
- Persistent urgency incontinence and urgency (8% to 25%) are more common presenting symptoms in bladder outlet obstruction after a PVS procedure than frank retention.
- A key to diagnosis is the temporal relationship between the anti-incontinence surgery and the onset of voiding symptoms. Urodynamic studies are essential in these cases to diagnose and make an appropriate treatment plan.
- Transient urinary retention usually resolves within 10 days, and obstruction from a PVS may improve or resolve with time; therefore most surgical interventions should be avoided until at least 6 months after surgery.
- Reported success rates of the surgical management of bladder outlet obstruction after a PVS procedure are 65% to 93%. There is a 0% to 19% recurrent SUI rate after urethrolisis.
- There are no preoperative variables that predict success or failure of urethrolisis. OAB symptoms are refractory in 50% of affected patients after urethrolisis and contribute to a significant portion of the reported failures.

sling procedures. In subsequent studies, most perforations and exposures were associated with synthetic slings, particularly woven polyester slings (Summit et al, 1992; Bent et al, 1993; Chin and Stanton, 1995; Weinberger and Ostergard, 1995; Myers and LaSala, 1998; Kobashi et al, 1999; Clemens et al, 2000; Duckett and Constantine, 2000; Amundsen et al, 2003). More recently, there have been a few reported cases of autologous and allograft sling perforations and exposures (Handa et al, 1999; Golomb et al, 2001; Amundsen et al, 2003; Bradley et al, 2003; Blaivas and Sandhu, 2004). See Table 84-7.

Most urethral perforations are diagnosed 1 to 18 months after the original surgery, with a mean presentation time of approximately 9 months (Blaivas and Sandhu, 2004). Presenting symptoms often include urinary retention, urgency, and mixed incontinence. In addition, synthetic sling perforations and exposures are also associated with vaginal discharge, vaginal pain, suprapubic pain, and recurrent UTIs. The etiology of these symptoms is usually multifactorial. One category of causes is local tissue factors—that is, postsurgical scarring, urethral atrophy, estrogen deficiency, and radiation-induced ischemia. The other category is surgical techniques—that is, excessive tension, dissection too near urethra, or perforation of the urethra or bladder.

Urinary tract perforation by an autologous PVS is rare. There are only four cases of perforation documented in the peer-reviewed literature. Handa and colleagues (1999) and Golomb and colleagues (2001) each reported an individual case of an autologous

sling eroding through the midurethra. **Colomb and colleagues (2001)** reported that the autologous sling eroded into midurethra after traumatic urethral catheterization for prolonged urinary retention. Other possible causative factors include misplacement or incorrect technique in sling passage or positioning, excessive tension, or traumatic urethral instrumentation after placement of a PVS (e.g., for hematuria clot evacuation or surveillance cystoscopy). In two of the aforementioned cases, the perforated portion of the sling was excised and the urethra was closed. **Clemens and colleagues (2000)** described two cases of bladder dome perforation by an autologous rectus fascial sling. The patients had recurrent UTIs, dysuria, and urgency incontinence. One of these patients had a bladder calculus on the sling material visible on cystoscopy. The other woman had edema and suture at the dome. In both cases, adequate cystoscopy with 30- and 70-degree lenses after Stamey needle passage may have avoided these complications. Both cases were successfully managed with endoscopic removal of stitches and treatment of the stone. No further treatments were necessary.

Management of autologous and allograft sling urethral perforation usually involves incision or excision of the part of the sling that has perforated and simple closure of the urethra (**Blaivas and Sandhu, 2004**). Rarely are additional coverage measures (e.g., Martius flap) required. **Because urinary tract perforation and vaginal exposure of synthetic PVSs are more common and associated with significant morbidity, synthetic material is no longer used for bladder neck slings.** In fact, the ProteGen sling (Boston Scientific) was withdrawn from the market in January 1999 possibly because of the high urinary tract perforation rates (**Clemens et al, 2000**). Some authors believe that synthetic PVS sling perforation into the urinary tract necessitates complete removal of the sling and all other foreign materials (sutures, bone anchors, screws) whenever present (**Blaivas and Sandhu, 2004**). However, we believe that as long as the synthetic material is no longer under tension and excised far away from the bladder, it is not necessary to remove all of the foreign material (except in cases of infection or severe pain). The technique for this removal is discussed in the MUS section.

The incidence of SUI after synthetic PVS removal for urethral perforation is 44% to 100%, and treatment often involves a secondary PVS (**Kobashi et al, 1999; Clemens et al, 2000; Amundsen et al, 2003**). In 2003, **Flisser and Blaivas** reported an 87% continence rate when perforations were managed with concurrent placement of a new PVS. In 2004, **Blaivas and Sandhu (2004)** also noted that secondary procedures such as periurethral bulking agents and PVSs are successful in a majority of patients. However, if the bladder neck is involved with the perforation, **Blaivas and Sandhu** noted a much lower overall continence rate, even with the use of concomitant autologous slings at the time of reconstruction.

Pubovaginal Sling Nonurologic Complications

The most common complications of the PVS are related to the urinary tract; however, there are significant nonurologic complications. The authors of the 2009 update of the AUA guideline for SUI surgery performed an extensive meta-analysis of the literature that included nonurologic complications (**Appell et al, 2009**). They found that the most common nonurologic complications were pulmonary, cardiovascular, neurologic, and gastrointestinal (bowel injury). In addition, the panel estimated a death rate of approximately 3 per 10,000 procedures, combining all SUI procedures (retropubic suspension, transvaginal suspensions, anterior repairs, and PVSs).

In 2007, **Anger and colleagues** analyzed Medicare claims data for short-term complications after sling surgery (mostly MUSs) among female beneficiaries aged 65 years and older (**Anger et al, 2007a**). From 1999 to 2001 a total of 1356 sling procedures were performed. In the 3 months after the procedure, 12.5% of women developed surgical or urologic complications, and 33.6% were diagnosed with UTIs. At 1 year after surgery, the following nonurologic complications were reported: bowel injury or obstruction (6.6%), cardiac complications (9.1%), thromboemboli complications (2.6%), pulmonary complications (15.3%), and other (22.1%). Multivariate analysis revealed that nonwhite patients were more

likely to experience urologic and nonurologic postoperative complications. In addition, women aged 65 to 69 years were significantly less likely to experience nonurologic complications or undergo treatment for outlet obstruction or re-treatment for incontinence than women older than 75 years.

More specific information about the type of complications can be gleaned by reviewing the literature. In the previously mentioned randomized controlled trial by **Albo and colleagues (2007)**, 326 women underwent autologous PVS procedures. In this population, rates of serious adverse events for the autologous PVS and Burch colposuspension groups were 13% and 10%, respectively. In the sling group, deep venous thrombosis (DVT) and serious bleeding both had an incidence of 0.3%. Although the authors did not describe the specific type of complication, there was also a 3.4% incidence of serious wound complications. The most common wound complications after autologous PVS surgery are wound infection, seroma, and incisional hernia. In their experience with over 500 patients, **Blaivas and Chaikin (2011)** reported a 1% rate of wound infections and a 1% rate of incisional hernias. In another retrospective study of 247 women from 2000, the rate of incisional hernias was a similar 0.8% (**Morgan et al, 2000**). Although rare, incisional hernias related to harvesting the rectus fascia are an unfortunate serious complication of autologous PVSs that usually require surgical correction.

KEY POINTS: COMPLICATIONS OF PUBOVAGINAL SLINGS

- The incidence of perforation is dependent on the sling material, with synthetic slings perforating 15 times more often into the urethra and exposing 14 times more often into the vagina than other materials. For this reason, the synthetic PVS is no longer used for support at the bladder neck.
- Synthetic sling vaginal exposures typically manifest with vaginal discharge, pain, suprapubic pain, and recurrent UTIs and require nearly complete removal.
- The incidence of recurrent SUI after synthetic PVS urethral perforation is 44% to 100%, and treatment often involves a second PVS.
- The perforation or exposure of autologous PVSs is rare.

MIDURETHRAL SLINGS

Mechanics, Anatomy, and Materials of Midurethral Slings

Mechanics of the Midurethral Sling

According to the integral theory, the most important factors in preserving continence are adequate function of the pubourethral ligaments, the suburethral vaginal hammock, and the pubococcygeus muscle (**Petros and Ulmsten, 1990**). An injury to any of these three components from surgery, parturition, aging, or hormonal deprivation can lead to impaired midurethral function and subsequently urinary incontinence. Urethral hypermobility is a symptom of damage to these normal supporting structures of the urethra and not a cause of SUI.

Preoperative ultrasonographic and MRI have demonstrated that the proximal urethra in patients with SUI is often open at rest and that regardless of urethral mobility, movement of the anterior and posterior walls of the urethra during stress most likely contributes to a shearing affect that opens the urethra and results in incontinence (**Sanders et al, 1994; Huang and Yang, 2003; Dietz and Wilson, 2004; Masata et al, 2006; Kociszewski et al, 2008**). Based on these observations, it appears that a MUS works by impeding the movement of the posterior urethral wall above the sling, directing its motion in an anteroinferior or anterior direction. In addition, inward movement of the posterior urethral wall after placement of a MUS results in urethral lumen narrowing (compression). This securing of the posterior wall of the urethra (with

or without compression during stress maneuvers) is one theory of how MUSs achieve continence.

In addition to this support of the urethra, some authors have proposed that MUSs work through a mechanism of dynamic urethral kinking during stress events. [Lo and colleagues \(2001\)](#) used ultrasonographic imaging to document evidence of urethral kinking during stress maneuvers.

Ideally, a retropubic or transobturator MUS is placed loosely at the midurethra. Its function does not require it to be tight. The sling is anchored in the endopelvic fascia for retropubic-directed slings and in the obturator internus and externus muscle and fascia for transobturator-directed slings. Over time the synthetic mesh sling becomes fixed in either of these two locations and provides support along its entire course inferior to the pubic symphysis and ischiopubic rami and not just at the midline area posterior to the urethra. This broad support might be the reason why in studies with more than 30 patients by [Laurikainen and Killholma \(2006\)](#), [Gamé and colleagues \(2006\)](#), [Clifton and colleagues \(2014\)](#) and [Klutke and colleagues \(2001\)](#), 50%, 70%, 79%, and 93% of women, respectively, remained continent after MUS incision for obstruction.

Several authors have found that for retropubic and transobturator MUSs, the lack of urethral mobility is a negative prognostic factor for a worse outcome in terms of cure of incontinence and that decreased urethral mobility postoperatively is associated with persistent incontinence ([Minaglia et al, 2005, 2009](#); [Haliloglu et al, 2010](#)). Also, the persistence of urethral hypermobility postoperatively is not associated with a worse outcome. It appears that lack of urethral mobility is an indication that the patient has a fixed urethra and ISD. Overall, patients without urethral hypermobility do not respond as well to MUS surgery. A loosely placed MUS combined with a mobile urethra may allow the sling to compress the urethra during times of Valsalva and stress while remaining nonobstructive when the urethra is at rest.

Despite the fact that transobturator and retropubic MUSs are placed without tension, there is controversy about whether tension or resistance is directed at the bladder outlet. In one study of 404 retropubic MUS procedures, urodynamic studies before and after surgery showed an increase in voiding time but no difference in flow rate, urethral closure pressure, or urethral functional length after MUS surgery ([Meschia et al, 2001](#)). A study by [Lo and colleagues \(2001\)](#) also showed no statistical difference in several urodynamic parameters (average flow, Qmax, PVR, MUCP, and functional urethral length) in 82 patients before and after retropubic MUS surgery.

In contrast, [Gateau and colleagues \(2003\)](#) analyzed pre- and post-retropubic MUS urodynamics in 112 patients and showed consistent decreases in Qmax, increased mean PdetQmax, increased mean urethral resistance, and elevated PVR urine. They concluded from their data that retropubic MUS leads to obstructive changes in the bladder outlet. [Sander and colleagues \(2002\)](#) evaluated the voiding phase before and 1 year after the retropubic MUS procedure. They found both subjective and objective changes in the voiding phase, with 78% of patients experiencing more difficult voiding and significant decreases in Qmax, corrected Qmax, and average flow. PVR urine was also significantly increased, although not greater than 25% capacity.

Unlike retropubic and transobturator MUSs, for single-incision MUSs it appears that restriction of urethral mobility after surgery is associated with a better outcome ([Martan et al, 2009](#)). [Martan and colleagues \(2009\)](#) analyzed 85 patients after a single-incision sling procedure with perineal ultrasonography. Efficacy was evaluated with a cough test and validated questionnaires. Objectively, 62% had a negative cough test result. The sling was noted to restrict urethral mobility, and a higher degree of restriction was associated with a higher likelihood of cure. This restrictive effect was noted to weaken within the first 3 months after surgery. A study of 57 patients who underwent single-incision MUS surgery from 2013 also showed that outcomes were worse in patients who had persistent urethral hypermobility after surgery ([Spelzini et al, 2013](#)). It is possible that the efficacy of single-incision slings is related to their restriction of urethral mobility and that this restriction is required to secure the posterior urethral wall, is required for adequate urethral kinking, or

results in compression of the urethral lumen. Of note, the authors have found that single-incision slings need to be placed tighter than other MUSs to achieve the desired effect.

Anatomy of the Retropubic Midurethral Sling

For a retropubic MUS, the trocars must pass through the retropubic space, which is also known as the *space of Retzius* or *prevesical space*. This space is bounded anteriorly by rectus abdominis muscles and the bony pelvis (pubic symphysis and ischiopubic rami). The lateral borders of the space are the bony pelvis and the obturator internus muscle. The bladder and proximal portion of the urethra lie posterior to this space. The endopelvic fascia (paravaginal connective tissue or pubocervical fascia) forms the inferior-lateral boundary of the prevesical space and is attached medially to the levator ani muscles at the bladder neck and inferior portion of the pubic symphysis. The endopelvic fascia is attached laterally to the ATPF and the ischiopubic rami. The endopelvic fascia separates the prevesical space from the vesicovaginal space. The prevesical space mainly contains loose connective tissue and adipose tissue. Obese patients may have more adipose tissue in this space, and this might contribute to the lower rate of trocar-related bladder injuries seen in this patient population ([Stav et al, 2010b](#)).

The left and right dorsal nerves of the clitoris (DNCs) run along the inferior surface of the ischiopubic rami and cross under the pubic bone approximately 1.4 cm from the midline ([Achtari et al, 2006](#)). After placing retropubic MUSs in 10 cadavers [Achtari and colleagues](#) found that the sling was an average 1.1 cm from the DNC at its closest point. The fact that the superior incisions for a retropubic MUS are typically made at least 2 cm from the midline should help ensure that a DNC is not injured by a trocar or sling. At a distance of 3.2 cm (laterally), the obturator vessels are the closest major vascular structures to a retropubic MUS ([Muir et al, 2003](#)).

The vesicovaginal space is the initial plane of dissection for a retropubic MUS. This space is bounded by the posterior wall of the bladder and the anterior wall of the vagina ([Corton, 2013](#)). The space extends to the proximal and middle urethra. Below this location, the posterior wall of the urethra and the anterior vaginal wall are fairly fused. A relatively thick periurethral fascia covers the posterior urethra. The female urethra is approximately 3 cm in length (therefore an incision 1.5 cm from the meatus is the midurethra).

Anatomy of the Transobturator Midurethral Sling

Like the retropubic MUS, transobturator MUS surgery begins with dissection in the vesicovaginal space. This dissection is carried out lateral to the urethra until the inferior border of the ischiopubic rami and pubic symphysis can be easily palpated. A trocar must traverse the obturator internus muscle, obturator membrane, and obturator externus muscle as it goes through the obturator foramen. Lateral to the obturator foramen are the adductor muscles (gracilis and adductor brevis muscles) of the thigh ([Corton, 2013](#)). The obturator nerve and vessels are located in the obturator canal at the superior aspect of the obturator foramen.

Several authors have performed cadaveric dissections to better understand the anatomic relationships of the transobturator MUS. [Delmas and colleagues \(2003\)](#) used the out-to-in approach on 10 female cadavers to detail the relevant pelvic anatomy in relationship to the sling insertion path. In this study, dissection demonstrated that the sling consistently passed 4 cm anterior and caudal to the obturator canal, confirming the relative safety of neurovascular structures. They also demonstrated that the sling traverses a plane between the perineal and levator ani musculature above the pudendal neurovascular pedicle.

In 2005, [Bonnet and colleagues](#) performed the in-to-out trans-obturator technique as described by [de Leval \(2003\)](#) in 13 cadavers to determine the sling path and proximity to surrounding structures. The authors noted that the sling never penetrated the adductor longus muscle and was a safe distance from neurovascular structures. However, in approximately 70% of studied cases, the implanted material did traverse the adductor magnus, adductor brevis, and gracilis muscles during its path into the pelvis. At the

level of the obturator foramen, the sling traverses the obturator externus and internus muscles as well as the obturator membrane. The distance between an inserted sling and the obturator nerve and vessels at the level of the obturator foramen ranged from 2.2 to 3 cm (mean 2.62 ± 0.2 cm). The authors stated that hyperflexion of the hip and the rotational trajectory of the helical passer help to ensure this separation. Also, the anterior branches of the obturator artery and vein are protected from injury by the bony architecture of the inferior pubic rami. Medially, the transobturator sling enters the anterior compartment of the ischiorectal fascia, in the area of the levator ani membrane and obturator internus muscle. A properly placed sling remains outside the pelvic space and does not penetrate the levator ani muscular group. Lastly, slings remain above the perineal membrane at all times and the DNC is found caudal to the perineal membrane and thus is protected from injury during trocar passage.

A study by Whiteside and Walters (2004) further evaluated the obturator anatomy in relationship to sling insertion in six female cadavers. These authors found that the mesh, on average, passed 2.4 cm inferior and medial to the obturator canal and that both divisions of the obturator nerve (anterior and posterior) were 3.4 cm and 2.8 cm, respectively, separated from the path of the trocar. However, they also noted that the trocar passed within, on average, 1.1 cm proximity to the most medial and anterior branches of the obturator vessels (the vessels described by Bonnet and colleagues behind the inferior pubic rami). These authors concluded that a risk of injury does exist and appropriate caution should be exercised.

The anatomic variation between the in-to-out and out-to-in transobturator MUS approaches has been compared, especially with regard to their association with adverse outcomes. Cadaver dissections after an in-to-out transobturator MUS placement noted that the mean distance from the vaginal incision to the obturator membrane was 4.0 cm, and from the vaginal incision to the obturator neurovascular bundle was 6.75 cm (Rogers et al, 2005). At the obturator membrane, the closest point of the passer is only a mean distance of 2 cm from the obturator neurovascular bundle. This is the reason the curved passer is directed away from these structures and advanced. Also, an anterior branch of the obturator artery coursed medially along the exterior edge of the obturator foramen in 60% of the cadavers. However, similar to Bonnet and colleagues (2005), Rogers and coworkers felt that the exterior bony rim of the obturator foramen protected this artery during an in-to-out pass, but they also postulated that this vessel could be potentially injured in an out-to-in approach.

Anatomy of the Single-Incision Midurethral Slings

For single-incision slings the plane of dissection is only in the vesicovaginal space. Although the trocars are much shorter, they are passed into the retropubic space or through the obturator foramen. As with the other MUSs, cadaveric dissection aids in the anatomic localization of the single-incision sling. Using 14 embalmed and 5 fresh-frozen female bodies, Hubka and colleagues (2009) placed single-incision MUS trocars bilaterally. After dissection, they measured the distances from the obturator bundle (obturator nerve and vessels) and found that the mean distances of the sling from the obturator nerve and vessels were 3.05 cm and 3.07 cm, respectively. Perforation of the fascia of obturator internus muscle occurred in 4.4%, and they felt that because of this, injury to variable vessels could theoretically occur. The position of the single-incision MUS was not found to change with repositioning of the legs.

Midurethral Sling Materials

In their initial description of the MUS from 1995, Ulmsten and Petros used Mersilene, Gore-Tex, Teflon, and Lyodura (cadaveric dura mater graft, linked to CJD transmission). However, because of complications related to other synthetic materials in the general surgery hernia literature, Ulmsten and colleagues (1998) eventually settled on a polypropylene multifilamentous woven mesh that they

termed the *intravaginal slingplasty* (IVS, Tyco Healthcare, Mansfield, MA) (1996). Currently, a soft, loosely woven, polypropylene monofilament mesh with a pore size exceeding $75 \mu\text{m}$ is the most commonly used material. As previously discussed, this material allows for optimal migration of host inflammatory components (leukocytes and macrophages) into the mesh for purposes of infectious surveillance and host wound healing (imbibition and inosculation). It was found that this material was also optimal for inciting fibrous tissue ingrowth. This type of mesh is known as a type I mesh (Amid classification) and has previously been described in the general surgical literature as being favorable from the standpoints of its mechanical properties (stretch and elasticity) (Dietz et al, 2001, 2003).

UraTape (Mentor-Porgés, Le Plessis-Robinson, France) was the first transobturator MUS, and outcomes related to its use were first reported by Delorme and colleagues in 2003. UraTape is a polypropylene microporous sling with a central silicone core. UraTape was eventually replaced by ObTape (Mentor-Porgés) because of a high rate of vaginal exposure, probably related to the silicone core. However, possibly because of its semi-microporous ($<50 \mu\text{m}$) properties, vaginal exposure problems have also been reported with ObTape (Siegel, 2005; Yamada et al, 2006). A second-generation transobturator sling developed by Mentor-Porgés is known as the Aris transobturator tape; it has a larger $200\text{-}\mu\text{m}$ pore size that allows improved tissue ingrowth with less encapsulation. A unique transobturator mesh is the BioArc, which has a biologic (porcine dermis, InteXen) graft material that is sutured on either end to the polypropylene mesh. The biologic material actually occupies a suburethral position (de Leval, 2003; Delorme et al, 2003). Table 84-8 displays the most commonly available MUS materials.

KEY POINTS: MECHANICS, ANATOMY, AND MATERIALS OF MIDURETHRAL SLINGS

- The integral theory states that the most important factors to preserve continence are adequate function of the pubourethral ligaments, the suburethral vaginal hammock, and the pubococcygeus muscle. An injury to any of these three components from surgery, parturition, aging, or hormonal deprivation can lead to impaired midurethral function and subsequently urinary incontinence.
- Urethral hypermobility is a symptom of damage to the normal supporting structures of the urethra and not a cause of SUI.
- The initial MUSs were made of materials with smaller pore sizes. Currently the majority of MUSs are made of loosely woven polypropylene.

Midurethral Sling Operative Procedures

Midurethral Sling Patient Counseling

Because MUS surgery involves the implantation of a synthetic, prosthetic material, surgeons should thoroughly counsel their patients about the permanent nature of these products and the unique and sometimes serious complications related to their use. Also, similar to the PVS, patients should also be counseled about the risk of transient and permanent voiding dysfunction after surgery. This should include a discussion of postoperative difficulty emptying the bladder and de novo urgency and frequency.

Midurethral Sling Anesthesia, Patient Positioning, and Preparation

MUS surgery can be performed using local (with or without sedation), spinal, or general anesthesia, but the final choice of

anesthesia is typically based on patient, surgeon, and anesthesia provider preference. In the original description of the MUS, local anesthesia was used so that the patient would be able to perform an intraoperative cough as a method of adjusting sling tension. It was believed that this would minimize the incidence of obstruction. However, multiple studies have failed to show a difference in the efficacy or safety of MUS performed with local versus spinal anesthesia (Wang and Chen, 2001; Adamiak et al, 2002). In one of those studies of 103 women who underwent MUS procedures, a comparison of local and spinal anesthesia was made; 67 women underwent the procedure with local and 36 with spinal anesthetic (Adamiak et al, 2002). In the postoperative evaluation there was no difference

in the success rate of the MUS surgery performed; there was also no difference in the rate of complications between the groups. However, there was a difference in the patients' ability to perform a cough test effectively during the procedure in the spinal anesthesia group, but this did not result in an increase in the rate of postoperative obstruction. It appears that tensioning the sling by cough stress test is not necessary.

As for the PVS, the AUA guidelines and Best Practice Policy Statements pertaining to antibiotic and DVT prophylaxis should be followed. Also, povidone-iodine or chlorhexidine gluconate solutions containing 4% or less alcohol (off-label) are both safe and effective for vaginal preparation. The MUS procedure is typically performed

with the patient positioned in the dorsal lithotomy position with a significant degree of flexion (70 degrees or more) of the thighs.

Surgical Approach for Retropubic Midurethral Slings

The device consists of two specially curved 5-mm diameter (size varies by manufacturer) insertion trocars that are attached to a 40-cm segment of polypropylene mesh that is 1.1 cm wide (size varies by manufacturer). The sling is typically covered with a clear plastic sheath, which protects the mesh from contamination and allows easy passage through host tissues. For the down-to-up technique, a rigid catheter guide is typically placed in the urethra with an 18-Fr Foley catheter to help deflect the bladder away from the path of trocar insertion. An ergonomic handle is attached to the trocar to aid in its manipulation. **Figure 84-8** shows some of the various types of slings and trocars.

For retropubic MUS insertion under local anesthesia with or without sedation, approximately 5 mL of local anesthetic is injected into the vaginal area as well as into the planned suprapubic insertion skin sites. In addition, another 20 mL of local anesthetic agent is injected into the area along the posterior aspect of the pubic bone to the level of the urogenital diaphragm to anesthetize the retropubic space. Additional vaginal infiltration includes 10 mL injected on either side of the urethra to the level of the urogenital diaphragm.

After appropriate anesthesia, two small suprapubic stab incisions are created just above the level of the symphysis pubis, approximately 2 cm lateral to the midline. A third midline vaginal incision approximately 1.5 cm long is created 1.5 cm from the external meatus of the urethra. After the vaginal incision is created, minimal dissection is performed using Metzenbaum scissors under the vaginal flaps on either side to elevate the vaginal epithelium from the underlying periurethral tissue to the level of the pubocervical (endopelvic) fascia, which is not perforated. For the down-to-up technique, the trocar is then placed in the dissection tunnel immediately beneath the vaginal epithelium on one side of the urethra with the trocar tip situated in close proximity to the lower rim of the pubic ramus. With controlled pressure, the trocar is elevated through the endopelvic fascia, into the space of Retzius, through the rectus muscles, and through the previously created suprapubic skin incision. During this maneuver, the trocar is kept in close contact with the inferior surface of the pubic bone to avoid perforation of the lower urinary tract and also to avoid intraperitoneal entry. Tactile contact with the bone and slow graded pressure during trocar advancement ensure direct apposition of metal to bone and avoidance of bladder injuries. The technique for up-to-down trocar passage is very similar; however, a catheter guide (Foley in urethra) is typically not used and the tip of the trocar is guided onto the index finger of the opposite hand and out of the vaginal incision lateral to the urethra.

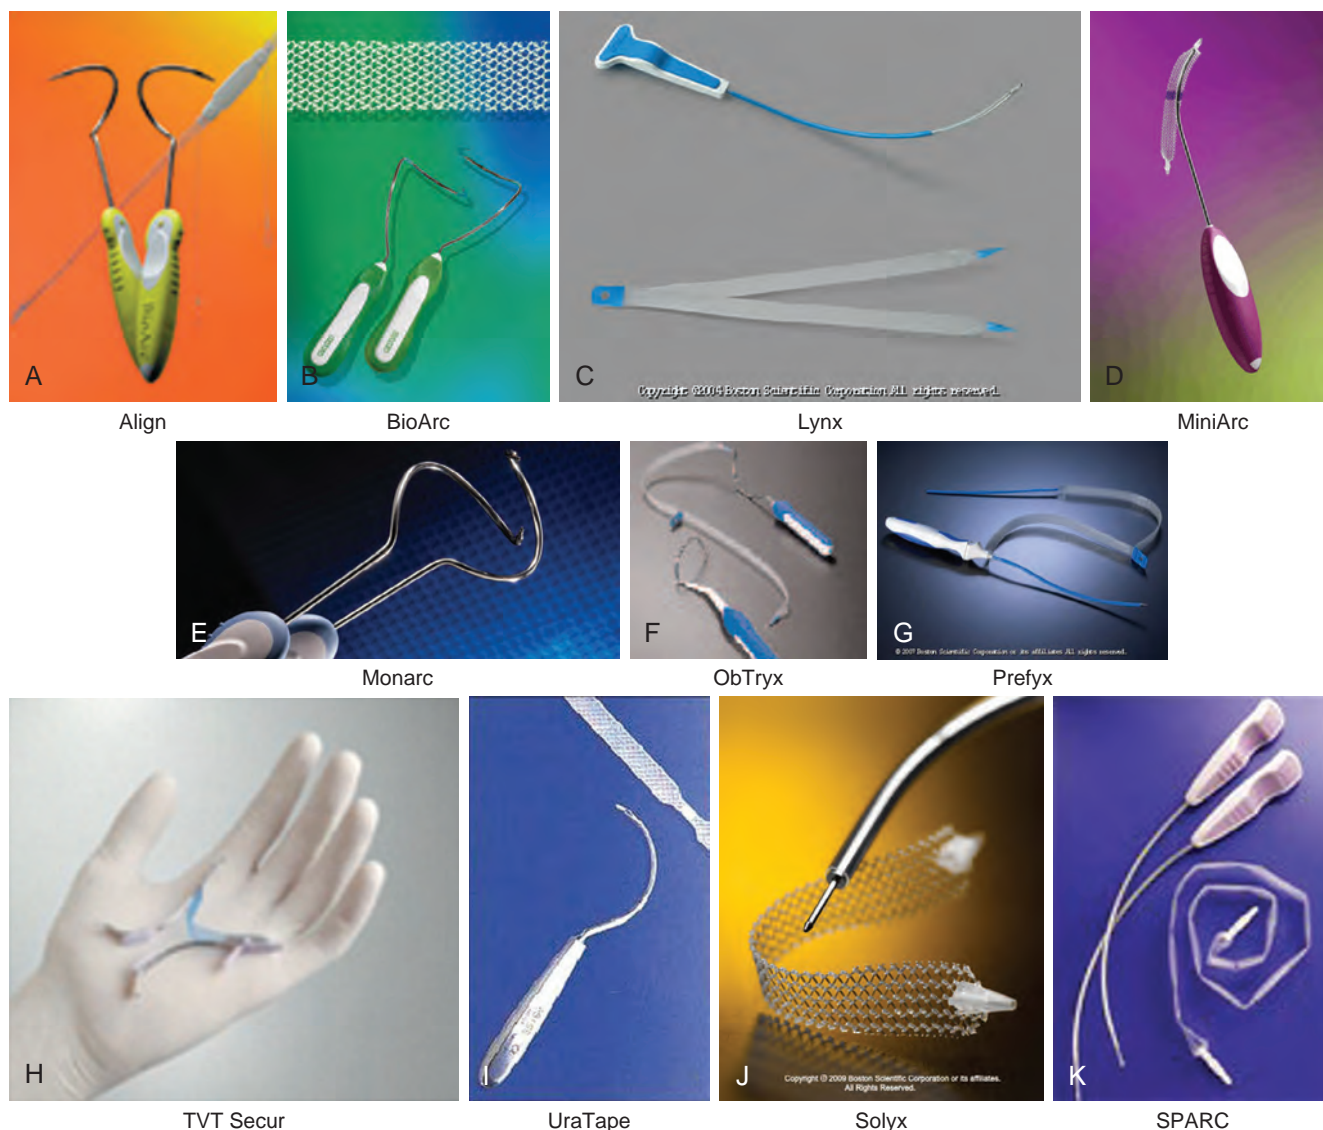

Figure 84-8. A-K, Midurethral sling trocars and prosthetics.

Simultaneous deflection of the lower urinary tract is accomplished during insertion using the catheter guide and catheter with pelvic viscera deflected away from the site of needle insertion. The same maneuver is performed contralaterally so that each trocar exits through the appropriate skin incision. **Cystoscopy is performed to exclude trocar penetration of the lower urinary tract.** The use of a 70-degree lens is essential, as is complete distention of the bladder with irrigant to exclude subtle tangential injury. **If perforation is noted, the trocar is withdrawn and passed once more with an effort to avoid further perforation.** Once cystoscopy has demonstrated no evidence of bladder injury, the mesh is brought through the incisions and tension adjustment of the sling is performed. Tension adjustment is commonly performed by inserting a surgical instrument (clamp) or metallic sound between the sling and urethra while the covering plastic sheath is removed from the field. **In general, a MUS should be placed loosely at the midurethra because its function is not primarily related to compression.** Redundant mesh is then excised at the level of the suprapubic skin incisions and all incisions are closed (Fig. 84-9).

Surgical Approach for Transobturator out-to-in Slings

The patient is placed in the dorsal lithotomy position with legs in hyperflexion (120 degrees). A small 1.5-cm midline vaginal incision is created 1.5 cm from the meatus as with the retropubic MUS, and dissection is carried out laterally to the ischiopubic ramus. A puncture incision is made in the obturator foramen at the level of the clitoris in the leg using the trocar; the obturator membrane is perforated, at which point resistance is noted by the operative surgeon. Using the nondominant index finger and identifying the landmarks of ramus and the obturator internus muscle, the trocar is turned in a medial orientation and advanced on the tip of the index finger and brought out through the vaginal incision. Inspection is carried out at this point to exclude inadvertent penetration of the vaginal fornix or associated urinary structures. The synthetic material is then attached to the trocar and brought out through the inner thigh stab wound. The procedure is then repeated on the contralateral side. Cystoscopy to rule out urethral and bladder injury is recommended

after trocar passage. **It is important not to neglect a careful examination of the urethra.** Tension is set on the sling by passing a clamp between the sling and urethra such that a surgical clamp can be passed easily between these two structures. Excess material is then cut at the skin puncture site and the incisions are closed according to the surgeon's preference.

Surgical Approach for Transobturator in-to-out Slings

The vaginal component of the procedure is the same as in the out-to-in technique. Stab incisions are created approximately 2 cm superior to the horizontal line level with the urethra and 2 cm lateral to the labial folds, which will be the exit point for the helical passer. Once the device is inserted through the urethra and the upper part of the ischiopubic ramus is reached with the device, the obturator membrane is perforated sharply with scissors. The introducer is then passed at a 45-degree angle relative to the midline sagittal plane until it reaches and perforates the obturator membrane. The open side of the introducer is passed out facing the surgeon. The more distal end of the tubing is then mounted on the spiral segment of the helical passer and slipped along the open gutter of the introducer. The passer is aligned parallel to the sagittal axis and rotated so that the tip of the tubing exits the inter-thigh stab incision. The tubing is then removed from the passer until the first few centimeters of the mesh become externalized, and the procedure is repeated on the contralateral side. Next, cystoscopy is performed to ensure no injury to the bladder or urethra. All plastic covering sheaths are then removed simultaneously from the sling while maintaining no tension on the sling itself, using the technique previously described. Operative technique varies with insertion method. Various procedures using similar insertion methods represent relatively similar technique (Fig. 84-10).

Surgical Approach for Single-Incision Slings

Each of the single-incision slings has a proprietary method of placement that varies by the manufacturer. In general, the sling devices consist of a short segment of loosely woven polypropylene mesh

Figure 84-9. Midurethral sling as placed via the retropubic approach.

Figure 84-10. Midurethral sling as placed via the transobturator approach.

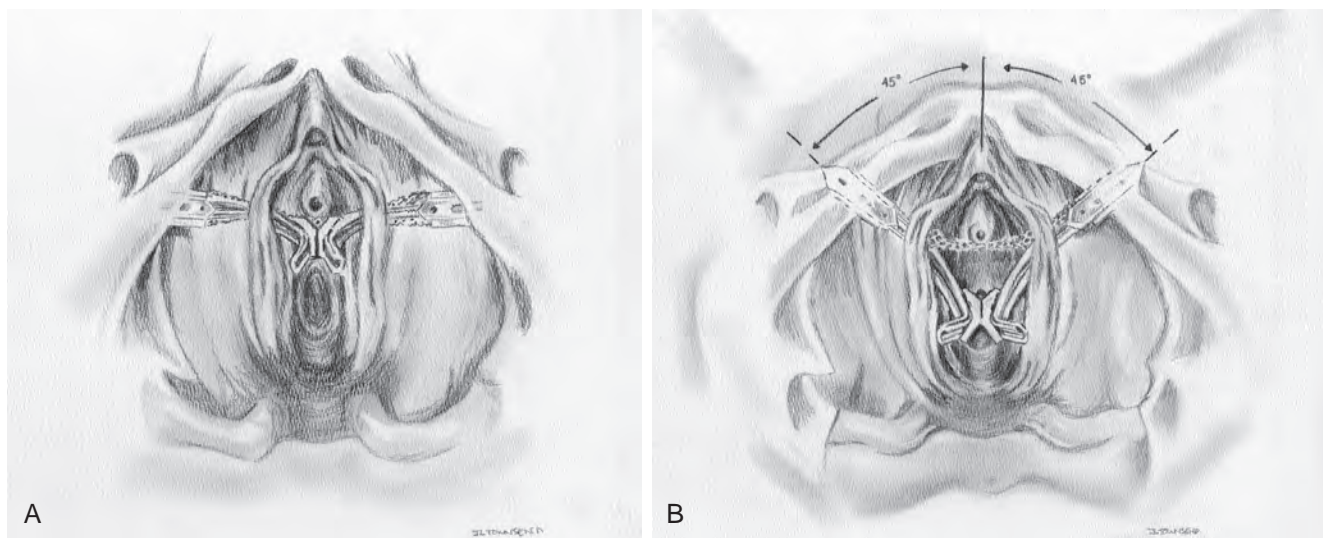

Figure 84-11. Midurethral sling as placed via a single-incision approach. **A**, Hammock style. **B**, U position.

with two harder pointed ends that allow it to anchor in place. A curved stainless steel trocar or other type of applicator device is used to push the ends of the sling into a secure position. The sling is placed under the midurethra and can be fixed in the hammock position (Fig. 84-11A) into the obturator internus muscle or in the U-shaped position (Fig. 84-11B) into the connective tissue of the urogenital diaphragm (endopelvic fascia) behind the pubic bone (Meschia et al, 2009).

The procedure is performed with the patient in the dorsal lithotomy position (with sequential compression devices in place) with a significant degree of flexion (70 degrees or more) of the thighs. A Foley catheter is placed before the procedure to ensure the bladder

is fully decompressed before passage of the device. As heretofore described, the patient has received parenteral sedation, and approximately 5 mL of 0.9% normal saline is used to hydrodistend the anterior vagina. After the vaginal incision is created, minimal dissection is performed using Metzenbaum scissors under the vaginal flaps on either side to elevate the vaginal epithelium from the underlying periurethral tissue to the level of the pubocervical fascia, which is not perforated. One trocar of the device is placed in the right dissection tunnel immediately beneath the vaginal epithelium and advanced up to the ischiopubic bone and into the obturator internus muscle, where the trocar holder anchors the sling edges. The left side is introduced in the same way, creating a

hammock-shaped sling. The definitive sling tension is achieved when the tip of a hemostat is easily passed between the urethra and the sling. Cystoscopy with a 30-degree rigid cystoscope should be performed before completion of the procedure. This step is essential to avoid the future morbidity of repeat surgery for intravesical or urethral mesh. Efflux of both ureteric orifices is confirmed. **Our experience suggests that the tension of single-incision MUSs should be tighter than the classic retropubic or transobturator MUS surgeries to achieve the same result.**

Outcomes of Midurethral Slings for Predominantly Stress Urinary Incontinence

In reviewing the extensive outcomes for the MUS, several caveats must be entertained. Outcomes are reported in varying fashions using different tools, lengths of follow-up, and overall definitions of success and failure. These factors should be kept in mind when attempting to compare different groups and procedural nuances.

Outcomes for Retropubic Midurethral Slings in Patients with Predominantly Stress Urinary Incontinence

The initial study of the retropubic MUS technique reported an 80% (author-defined) success rate (Ulmsten et al, 1996). A subsequent prospective multicenter trial that included 130 women with genuine stress incontinence who were observed for 1 year revealed success, improvement, and failure rates of 91%, 7%, and 2%, respectively (Ulmsten et al, 1998). In this first multicenter study, complication rates were low but did include one bladder mesh perforation and one wound infection (possibly mesh exposure). The rate of voiding dysfunction was also relatively low, with only 1 patient experiencing retention for 12 days, which resolved spontaneously, and 3 patients with less than 3 days of voiding dysfunction that required short-term catheterization.

In 2001, Nilsson and Kuuva (2001) evaluated 161 consecutive retropubic MUS operations (28% of patients had failed prior incontinence surgery, 11% had ISD, and 37% had mixed incontinence). At 16 months' mean follow-up the overall objective cure rate was 87%, with 7% of patients significantly improved and another 5% of procedures considered failures. The trocar bladder injury rate at the time of insertion was 3.7%, and 4.3% of women experienced short-term de novo voiding dysfunction. Urgency symptoms arising after surgery occurred in 3% of women, yet 80% of the women who had preoperative urgency symptoms had relief of those symptoms at their 16-month visit. No serious complications were noted.

Long-term results mirror the short-term experience with this procedure. Success rates ranging from 81% to 90% have been reported at more than 3 years. Ulmsten and colleagues (1999) reported an 86% success rate in 50 women at 3 years. Olsson and Kroon (1999) reported 90% success in 51 women at 3 years. Doo and colleagues (2006) evaluated the long-term efficacy and safety of this procedure among 134 Korean women. The overall 5-year success rate was 94.9%, with an 86.6% patient satisfaction rate. Although success rates between 1 and 5 years were similar (97.7% and 94.9%), the cure rate decreased from 90.1% to 76.9%. Nilsson and colleagues (2001) reported success rates of 84.7% at 5 years and 81.3% at 7 years (Nilsson et al, 2004) in a cohort of 90 women. Liapis and colleagues prospectively assessed the efficacy of the MUS in 65 women. At 5-year follow-up, the objective cure rate was 53% and the failure rate was 9.4%, whereas at 7-year follow-up the objective cure rate was 80% and the failure rate was 13.5% (Liapis et al, 2008). Song and coworkers (2009) reported on the second longest follow-up (>7 years) in 306 women, with a cure rate of 84.6%. They reported on 6 patients who developed mesh exposure.

As a continuation of their earlier work, Nilsson and colleagues (2008) provided the longest (11 years) prospective observational cohort study of 90 women with primary stress incontinence. Ninety percent of these women were objectively cured, and 77% of the

patients reported subjective cure. No late-onset adverse effects or cases of mesh erosion were seen. The Austrian Urogynecology Working Group (Tamussino et al, 2001) published their data compiled within the Austrian central registry, beginning in 1998. There were no serious complications and no mortality within the registry. It is interesting to note that 363 (45%) of the patients in the registry had a MUS in combination with other procedures (prolapse repair). All of these long-term studies attempted to evaluate risk factors for declining effectiveness, and in general there does appear to be a tendency for higher failure rates in older patients and patients with diminished urethral function (ISD).

Over a dozen randomized clinical trials have compared the retropubic MUS with traditional incontinence procedures in published peer-reviewed journals. This includes five comparing MUS with open colposuspension (Ward and Hilton 2002, 2004; Bai et al, 2005; El-Barky et al, 2005; Ward and Hilton, 2008), four comparing retropubic MUS with laparoscopic colposuspension (Persson et al, 2002; Ustun et al, 2003; Paraiso et al, 2004; Valpas et al, 2004), two comparing retropubic MUS with a fascial sling (Bai et al, 2005; Wadie et al, 2005), and one comparing retropubic MUS with no treatment (Campeau et al, 2007). Table 84-9 displays the outcomes of retropubic MUS surgeries from randomized controlled trials.

Among the retropubic MUS versus Burch comparisons, the trials by Ward and Hilton (2002) and Valpas and colleagues (2004) enrolled the greatest number of patients. The Ward and Hilton trial that compared retropubic with open colposuspension published data at short-term (Ward and Hilton, 2002), intermediate-term (Ward and Hilton, 2004), and long-term (Ward and Hilton, 2008) follow-up. At 6 months' follow-up, the 344 women randomized to retropubic MUS (175 patients) and Burch arms (169 patients) demonstrated no significant difference in cure rates. The MUS was associated with more operative complications (i.e., bladder trocar injury), and the colposuspension was associated with more postoperative complications and longer recovery. At 2 years' follow-up, the overall cure rates noted were relatively low, with 63% of the MUS surgery patients and 51% of colposuspension patients being cured (Ward and Hilton, 2004). Also, there were significantly more patients in the colposuspension group needing intermittent self-catheterization (<0.0045) and surgery for pelvic organ prolapse (<0.0042) than in the MUS group. At long-term follow-up (5 years), there was no difference in cure rates. Consistent with earlier studies, prolapse was seen more commonly in Burch group. Two mesh exposures were found in the retropubic MUS group. Unlike earlier reports of high (27%) rates of de novo urgency and urgency incontinence in the literature (Jarvis, 1994) after colposuspension, Ward and Hilton reported that less than 2% of patients after MUS and less than 5% of patients after colposuspension experienced this problem (Ward and Hilton, 2008). Ward and Hilton (2002) and El-Barky and colleagues (2005) (another study of retropubic MUS vs. Burch colposuspension) found operation time, hospital stay, and time until return to normal activity significantly shorter in the MUS groups. El-Barky and coworkers (2005) reported two bladder trocar injuries in the MUS group, whereas wound infections were significantly more common among the Burch patients.

Bai and colleagues (2005) compared MUS surgery with open colposuspension and autologous PVS. At 3- and 6-month follow-up, there were no differences in cure rates among the operations, but at 12 months the PVS had significantly higher cure rates (92.8%) than the colposuspension (87.8%) or MUS (87.0%). In a 2005 comparison of the MUS and the PVS, Wadie and colleagues (2005) found the PVS and MUS to be equally effective. Lastly, the MUS may be more cost-effective and superior in terms of impact on health care spending compared with open colposuspension (Manca et al, 2003).

Four randomized trials (Persson et al, 2002; Ustun et al, 2003; Paraiso et al, 2004; Valpas et al, 2004) have been performed comparing retropubic MUS surgery with laparoscopic colposuspension. Valpas and colleagues and Persson and colleagues reported results after 12 months of follow-up, and Paraiso and colleagues reported outcomes at 18 months. The results of these trials revealed MUS cure rates ranging from 86% to 97% and colposuspension cure rates

ranging from 57% to 100% (variable methods of reporting). There was no apparent difference between the two procedures in the Persson and colleagues trial, but Paraíso and colleagues and Valpas and colleagues noted that the MUS surgery resulted in significantly higher rates of success in terms of urinary incontinence. These trials noted no other apparent differences between techniques other than that the MUS group recovered more rapidly and had a lower need for subsequent urogenital prolapse procedures than the colposuspension group. However, [Dean and colleagues \(2006\)](#) reviewed seven randomized trials comparing MUS and laparoscopic colposuspension and found no statistically significant difference in reported subjective cure rates within 18 months, but the overall objective cure rate was significantly higher for retropubic MUSs.

[Novara and colleagues \(2008\)](#) performed a meta-analysis of 33 randomized controlled trials comparing retropubic MUSs with other anti-incontinence procedures. Complications were similar

between MUS and Burch colposuspension, with exception of bladder trocar injury (higher in MUS group) and reoperation rate (higher in Burch arm). Retropubic MUSs and PVSs were found to be equally effective, with better cure rates than the Burch colposuspension ([Novara et al, 2008](#)).

A number of randomized studies exist comparing different types of retropubic MUSs. Three trials compared the Gynecare TVT with the Suprapubic Arc Sling (SPARC), a polypropylene mesh material approaching the midurethra from the abdominal incision ([Andonian et al, 2005](#); [Tseng et al, 2005](#); [Lord et al, 2006](#)). [Tseng and colleagues \(2005\)](#) found the Gynecare TVT and SPARC to be equally effective. The SPARC group had a greater number (12.9%) of bladder trocar injuries than the Gynecare TVT group (0%). Although this was not statistically significant, the authors felt it was clinically significant. In 2005, [Andonian and colleagues \(2005\)](#) randomized 84 patients to either arm and found no statistically

significant difference between SPARC and Gynecare TVT in terms of objective cure rates at 12 months' follow-up. Mesh exposure, infected pelvic hematoma, and UTI were found postoperatively only in the SPARC group, but there were no differences in other perioperative complications (bladder trocar injury, blood loss, hospital stay, urinary retention, postoperative analgesia). [Lord and colleagues \(2006\)](#) found the Gynecare TVT group to have a lower rate of vaginal exposure (4.8% vs. 10.5%) and a statistically significantly higher subjective cure rate (87.1% vs. 76.5%) than the SPARC group. In addition, the authors found the SPARC to be more difficult to adjust correctly, and a statistically significant number of patients required loosening of the sling ($P = .002$).

[Arunkalaivanan and Barrington \(2003\)](#) compared the Gynecare TVT with allogenic acellular porcine collagen, Pelvicol (C.R. Bard), in a questionnaire-based study. They reported on both 12-month and 36-month results and found no difference in subjective cure rates. Gynecare TVT was compared in three studies with IVS, a multifilament, microporous polypropylene mesh material, which is passed similarly to a SPARC. [Rechberger and colleagues \(2003\)](#) reported no differences in cure rates at 13 months' follow-up with 50 patients in each group. With exception of postoperative acute urinary retention occurring significantly more commonly among the Gynecare TVT patients, complications were similar. [Meschia and colleagues \(2006\)](#) compared the TVT and IVS with intermediate follow-up and reported subjective cure rates of 80% (Gynecare TVT) and 78% (IVS) and objective cure rates of 85% (Gynecare TVT) and 72% (IVS). Eight (9%) of the IVS patients experienced vaginal erosion, with none found in the Gynecare TVT group. The TVT was compared with the IVS and SPARC by [Lim and colleagues \(2005\)](#) in the SUSPEND trial. There was no significant difference between the cure rates: 87.9% (Gynecare TVT) versus 81.5% (IVS) and 71.4% (SPARC). There was a significantly greater rate of mesh exposure in the SPARC group. [Balakrishnan and colleagues \(2007\)](#) followed a subgroup of IVS patients from the [Lim group \(2005\)](#) for up to 30 months and found 13% with sling erosions, requiring removal. Of the 29 patients (47%) from this initial IVS group seen 12 to 34 months postoperatively, 24% experienced sling erosion with associated sinus formation, requiring sling removal. In the [Novara and](#)

[colleagues \(2007\)](#) meta-analysis, the Gynecare TVT was found to be more efficacious than the IVS and SPARC.

Outcomes for Transobturator Midurethral Slings in Patients with Predominantly Stress Urinary Incontinence

Subsequent to the development of the retropubic MUS, it was recognized that the transobturator MUS approach was also a viable method for correction of SUI. Since the initial description of the transobturator MUS by [Delorme in 2001](#), continence rates have been reproducibly satisfactory ([Table 84-10](#)). Reported continence rates range from 40% to 97% on the basis of a variety of subjective (questionnaire and QoL single-item assessment) and objective (cough stress test, uroflowmetry, physical examination) measures. Overall, the outcomes of transobturator MUS procedures in patients with predominantly SUI are similar to those of the retropubic MUS.

Many prospective randomized studies have compared transobturator with retropubic MUS procedures, ranging in follow-up from 6 to 31 months ([Lee et al, 2007b](#); [Porena et al, 2007](#); [Zullo et al, 2007](#); [Rinne et al, 2008](#); [Schierlitz et al, 2008](#); [Rechberger et al, 2009](#); [Richter et al, 2010](#)). Between the two groups there were a significantly greater number of bladder trocar injuries in the retropubic versus the transobturator patients: 6.5% versus 0% ([Rechberger et al, 2009](#)) and 7.3% versus 0% ([Schierlitz et al, 2008](#)). Both of these groups also found the retropubic MUS to be more effective than the transobturator MUS in patients with ISD. Schierlitz and colleagues observed that at 6-month follow-up, 13% of the transobturator patients with ISD required further surgery, whereas 0% of the retropubic MUS patients with ISD required reoperation for SUI ([Schierlitz et al, 2008](#)). Porena and colleagues noted that incontinence was significantly improved in the transobturator MUS group (still present in 24%) but persisted in 44% of the retropubic MUS group ([Porena et al, 2007](#)). A few key points are consistent between these studies: these techniques were safe, there were no long-term complications in either group, cure rates were equal (with the exception of the ISD group), and patients were equally satisfied.

In 2010, [Richter and colleagues](#), published results of the prospective randomized trial comparing the retropubic MUS with the transobturator MUS with 12 months of follow-up. In this study, 298 women underwent a retropubic sling procedure and 299 underwent a transobturator sling procedure. The objective cure rates in terms of a negative stress test, pad test, and no re-treatment for the retropubic and transobturator groups were 80.8% and 77.7%, respectively (no statistically significant difference). The rate of voiding dysfunction requiring surgery was significantly higher in the retropubic group (2.7% vs. 0%).

Outcomes for Single-Incision Midurethral Slings in Patients with Predominantly Stress Urinary Incontinence

Surgical treatment of SUI has expanded to include single-incision slings. This technology was first approved (Gynecare, TVT Secur) by the FDA in 2006. There are fewer data available regarding the safety and efficacy of this new generation of slings compared with the retropubic and transobturator MUSs.

[Neuman \(2008\)](#) performed a prospective observational study of 100 consecutive women with a hammock-style single-incision sling. The perioperative and 12-month postoperative data were compared between the first 50 patients and the last 50 patients. The objective failure rate went down from 20% to 8% between the two groups, with the sling being placed closer to the urethra. Four (8%) patients in the first group had vaginal perforation with the inserter. This was avoided in the second group by widening the submucosal tunnel. The mesh exposure rate decreased from 12% to 8% by the creation of deeper submucosal tunnels. There was one case of a paravesical self-remitting hematoma. Otherwise, the authors reported no cases of bladder or urethral perforation, UTI, wound infection, or intraoperative bleeding. At 12-month follow-up, the objective cure rates between the two groups were 88.6% and 93.5%.

In 2009, [Dmochowski and colleagues](#) reported preliminary results on one of the largest trials of the single-incisions MUS, with 29 sites in 8 countries. Effectiveness was measured by a standing cough stress test and an Incontinence Quality-of-Life instrument (I-QOL). In this study, 642 women were studied; 64.5% had a hammock (fixed into the obturator internus muscle) placement and 35.5% had the U (fixed into the endopelvic fascia toward the retropubic space) placement of the sling. Also, 65.3% had genuine SUI and 34.7% had MUI with predominantly stress symptoms. Intraoperative complications noted included 1 bladder perforation (0.2%) and 3 cases of bleeding exceeding 200 mL (0.5%). Postoperatively, there was 1 reported case of retention (0.2%), 10 UTIs (1.6%), 6 cases of voiding dysfunction (0.9%), and 15 cases of de novo urgency (2.3%). There were 5 cases of mesh erosion (0.8%). Improvements in QoL at 3 months were sustained at 12 months. Objective incontinence rate with the cough test was 11% at 6 months and 12.5% at 12 months, giving an objective cure rate of 87.5%.

Also in 2009, [Pickens and colleagues](#) presented their initial experience with 120 MiniArc cases at 13-month follow-up. Success was defined as using no pads, with subjective outcomes assessed with the IIQ-7 and UDI-6 questionnaires. Thirty-five percent had concurrent UUI. At 13 months, 94% had complete resolution of SUI and 6 reported significant improvement; 1 patient had a treatment failure. Twenty-four percent reported resolution of their UUI. Three (0.4%) intraoperative bladder perforations were reported. Two patients experienced retention postoperatively; in 1 the condition resolved, and the other patient underwent urethrolisis because of persistent retention.

[Krofta and colleagues \(2009\)](#) analyzed the efficacy and safety of the TVT Secur sling in 82 women through use of a cough stress test and validated questionnaires. There were no major perioperative complications or cases of urinary retention reported. Two patients had UTI (2.9%) and 4 wound infections (5.8%) within the first week after surgery. Mesh erosion occurred in 4 patients (6%). Subjective outcomes were cure of 58.2%, 23.9% improvement, and 17.9% failure. Objective cure rate was 51.5%. A second anti-

incontinence procedure was performed in 8 patients (6 retropubic MUS, 2 Burch colposuspension). These authors felt that the single-incision MUS was inferior to other MUS procedures.

In a prospective, multicenter study of 154 women with single-incision slings, [Debodinance and colleagues \(2009\)](#) reported cure rates of 70.3%, improvement in 11%, and failure in 18.7% at 1-year follow-up; 31.8% had MUI. Perioperative complications included 5 hemorrhages, 1 bladder injury, 1 vaginal wound, 21 cases of elevated PVR volume, and 1 case of persistent groin pain. Two patients returned with vaginal exposure of mesh and 1 with a granuloma; 61.1% reported cure of their urgency, and 12.3% reported de novo urgency. The overall cure rate did not change between 2 months and 1 year.

[Meschia and colleagues \(2009\)](#) used multiple validated questionnaires and cough test to assess 91 women at 1-year follow-up after placement of a single-incision sling. Fifty-five patients had a sling placed in the hammock position and 40 patients in the U position. The researchers reported subjective and objective cure rates of 78% and 81%, respectively. No bladder perforations were encountered. Two patients had intraoperative hemorrhage greater than 500 mL. Postoperative complications included 7 women with voiding difficulty (8%), 9 with recurrent UTI (10%), 9 with de novo urgency (10%), and 2 vaginal exposures. Among the 20 failures, 8 patients went on to have a second anti-incontinence procedure (5 retropubic MUS, 2 transobturator MUS, 1 Reemex implant).

Several studies have compared single-incision slings with standard MUSs (retropubic or transobturator). The largest of these is a 2011 study by [Tincello and colleagues](#) using the TVT Worldwide Observational Registry. This study compared 12-month outcomes of the different sling types (TVT Secur, Gynecare TVT, and the TVT Obturator System) in 1334 women. The primary outcome measures were the standing cough stress test, the I-QOL questionnaire, and the EQ-5D. The baseline characteristics including proportions of MUI were similar. Single-incision sling patients returned to normal activities quicker than those who received either the retropubic or transobturator MUS. Satisfaction rates were similar among the three groups. Objective cure rates were as follows: 84.2% for single-incision sling, 87.2% for retropubic MUS, and 96.4% for transobturator MUS. With regard to complications, all three techniques were similar.

[Basu and Duckett \(2010\)](#) performed a prospective, randomized controlled trial of the retropubic MUS versus the MiniArc single-incision sling in 70 women with 6 months' follow-up. The MiniArc group had statistically lower subjective cure rates and urodynamics stress incontinence cure rates than the retropubic MUS group (63.3% vs. 100% and 45% vs. 93%). At 6-month follow-up, 50% of the MiniArc patients had urodynamic SUI versus 7% in the retropubic group.

In 2010, [Hinoul and colleagues](#) performed one of the first randomized controlled trials comparing the transobturator MUS versus the single-incision sling. In this 12-month study, data were available for 160 randomized women (85 TVT-O and 75 TVT Secur); QoL and subjective outcomes were reported using validated questionnaires. One bladder perforation occurred in the transobturator MUS group. The objective cure rates for the transobturator MUS were significantly higher than for the TVT Secur (97.6% vs. 83.6%, $P < .05$); however, the TVT Secur surgery was associated with less pain in the first week postoperatively. This pain difference disappeared within 2 weeks.

Also in 2011, [Abdel-Fattah and colleagues](#) performed a meta-analysis to examine the effectiveness and safety of single-incision versus other MUS surgeries. The authors found nine randomized controlled trials comparing these two operations that included a total of 758 women with a mean follow-up of 9.5 months. The authors found that single-incision slings were associated with significantly lower subjective and objective cure rates than other MUS surgeries. The authors concluded that this form of therapy was inferior to the standard MUSs.

There is evidence in the literature that single-incision slings have decreasing efficacy with longer follow-up. In a 2012 study

TABLE 84-11 Outcomes with Single-Incision Midurethral Slings (Randomized Controlled Trials)

by Han and colleagues of 96 women prospectively followed after TVT Secur surgery, a significant decrease in subjective cure rate was seen between years 1 and 3 (85.4% to 72.9%). In another study from 2012 by Masata and colleagues with 2 years of follow-up, 197 women were randomized to receive single-incision sling surgery or transobturator MUS surgery. The authors found that the single-incision sling had significantly lower objective and subjective cure rates (objective 69.0% vs. 92.6%; subjective 75.2% vs. 89.7%). Table 84-11 displays the outcomes of single-incision sling surgeries from randomized controlled trials.

Outcomes of Midurethral Slings for Mixed Urinary Incontinence

Evidence suggests that MUSs are successful for women with mixed urinary symptoms as well. However, interpretation of these studies should be judicious because many outcomes are reported on the basis of symptoms only, with no urodynamic substantiation. In a retrospective analysis of 112 consecutive women with SUI and mixed incontinence by Jeffry and colleagues from 2002, the objective cure rate measured by clinical and urodynamic examination was 89.3% at a mean follow-up of 25 months. Objective cure was defined as no evidence of stress incontinence, a negative stress test result, and no urinary retention or PVR volume greater than 150 mL. No difference was found in the objective cure rate between patients with SUI and those with mixed incontinence. The overall subjective cure rate determined by the Contilife questionnaire was 66%. Subjective cure was lower than objective cure in both SUI patients and patients with mixed incontinence—69.3% and 54.2%, respectively. The type of incontinence did not alter the incidence of postoperative voiding difficulty. Ten of the 24 patients with mixed incontinence had persistence of the urgency component.

Holmgren and colleagues (2005) evaluated the outcome of the retropubic MUS in women with stress and mixed incontinence with mailed questionnaires 2 to 8 years postoperatively. This was a large cohort of 970 women, and the 78% response rate was remarkable; 580 women with stress incontinence and 112 women with mixed incontinence were eligible for analysis. However, urodynamic studies were not performed in these women, and therefore categorization of their incontinence was based only on a positive stress test result and a history of leakage immediately preceded by urgency. Specific questions regarding stress and urgency incontinence were posed, and respondents selected options including worsened, unchanged, improved, almost cured, and cured. For analysis, the women were grouped into cohorts by the number of years since they had undergone retropubic MUS surgery. The mean age of women with mixed incontinence was significantly greater than the mean age of women with stress incontinence (67 years vs. 61.2 years). Adjustment for age was made in the analysis. In addition,

women with mixed incontinence had a statistically significant higher body mass index (BMI), rate of cesarean delivery, history of radiation, and prevalence of urinary frequency than those with stress incontinence. The 580 women with genuine SUI had a durable 85% subjective cure rate after 3 and 8 years of follow-up. However, only 60% of the 112 women with mixed incontinence were cured 3 years after surgery, and outcomes declined steadily thereafter. By 6 to 8 years postoperatively, the cure rate in women with mixed incontinence was only 30%. In addition, urgency and episodes of urgency incontinence increased with time after the MUS. In the final analysis, the lower cure rate in the patients with mixed incontinence may be a result of the other variables in this population such as age, cesarean section, radiation, and higher BMI. These differences in the populations confound the ability to assess outcome and highlight the limitations of this study design. Overall, despite the population variables, early outcomes of MUS are good and equal in women with stress incontinence and those with urgency incontinence. The diminishment of results over time needs to be confirmed by a prospective study (Holmgren et al, 2005).

In a similar Finnish study, 191 women who had undergone MUS were evaluated by examination or telephone interview for outcome at a mean follow-up of 17 months (Laurikainen and Killholma, 2003). Sixty-four (34%) of these women had preoperative MUI. None of the women had preoperative urodynamic evaluation; instead, the preoperative diagnosis was based on symptoms. Cure after MUS was judged as self-report of being completely dry in any stress situation. At latest follow-up, 164 of the 191 patients were completely cured, for a cure rate of 87.7%. The cure rate in women with mixed incontinence was 69% compared with a cure rate of 97% in the women with genuine stress incontinence. This outcome difference was statistically significant. No difference in cure rate was found between women who had undergone concomitant surgery or MUS alone. Sixty percent of the women with mixed incontinence considered themselves improved from an urgency incontinence perspective as well. The lower cure rate in the mixed incontinent patients is not fully known. No description of the preoperative physical examination is given, and it is not known how many of them were among the 149 (78%) who had urethral hypermobility. The authors suggested that on the basis of these results, preoperative urodynamic studies should be performed in women with mixed incontinence before anti-incontinence surgery.

Segal and colleagues (2004) evaluated 98 women after MUS explicitly to answer the question of what happens to urinary urgency incontinence. The outcome of MUS procedures in women with mixed incontinence or significant stress incontinence with associated frequency and urgency was assessed retrospectively by a variety of methods: subjectively by patients' symptoms, by the rate of anticholinergic use before and after MUS, and by before and after QoL questionnaires. One strength of this study is that patients with concomitant surgery were excluded to minimize the confounding

effect of other causes on urinary urgency incontinence or frequency and urgency. Sixty-five women were identified as having urgency incontinence, and follow-up occurred at 3 months and 1 year. Several preoperative factors were looked at for risk of postoperative frequency, urgency, or urgency incontinence requiring anticholinergics. On the basis of preoperative subjective symptoms, the urgency component was found to be resolved in 63.1% after MUS. Two patients with complaints of urgency incontinence only but stress incontinence identified on urodynamic studies had persistent urinary urgency incontinence requiring anticholinergic drug treatment. Seventy-five patients had preoperative urinary frequency and urgency, which resolved in 57.3% after MUS. It is interesting to note that 30 (57.7%) of the 52 patients requiring anticholinergic medications preoperatively no longer needed medication after surgery. Only 4 (4.1%) patients needed anticholinergics for the first time after MUS. Of all the variables assessed as possible risk factors for postoperative OAB requiring an anticholinergic, only a history of prior anti-incontinence surgery was statistically significant. Patients with prior surgery were eight times more likely to have postoperative OAB requiring use of anticholinergics. Overall, the resolution of preoperative urgency incontinence was 63% and resolution of preoperative urinary frequency and urgency was 57.3%. Resolution based on no longer needing anticholinergic medication postoperatively was 57.7%. MUS surgery resulted in statistically significant improvement in QoL scores postoperatively in women with stress-predominant mixed incontinence and stress incontinence with urinary frequency and urgency (Segal et al, 2004).

Rezapour and Ulmsten (2001) reported their 5-year data on the efficacy and safety of MUS in women with mixed incontinence. In all of these women the urgency component was sensory, and no woman had urodynamic evidence of DO. Eighty women were evaluated and reported in a retrospective fashion. All had undergone urodynamic evaluation preoperatively and all were found to have stress incontinence as well as motor detrusor contractions during filling. At follow-up, 85% were reported as cured and an additional 4% had improved symptoms on the basis of pad testing and symptom questionnaire. The researchers concluded that urodynamic studies were essential before surgery to analyze presenting symptoms. Only one patient had prolonged retention (6 weeks), but 8% were found to have small hematomas and one patient required exploration for bleeding.

In 2008, Paick and colleagues reported short-term outcomes of retropubic and transobturator MUS surgeries in women with MUI. There was no significant difference in cure rates for SUI. Preoperative DO was an independent risk factor for treatment failure of the urgency incontinence component. Athanasiou and colleagues (2009) compared the efficacy of retropubic and transobturator MUSs for treatment of urinary incontinence in women with MUI and idiopathic DO. There were no subjective differences in outcome, yet women undergoing retropubic MUSs were less likely to have persistent DO postoperatively.

Kulseng-Hanssen and colleagues (2008) evaluated outcomes of retropubic MUS procedures in 1113 women with MUI based on the patient's predominant bothersome concern—that is, stress incontinence, urgency incontinence, or stress and urgency incontinence equally. There were no differences in cure rates among the three groups. Predominant stress incontinence had significantly better results at 7 and 38 months than the other two groups, especially the patients reporting mainly UII. Eleven percent of women had an increase in urgency incontinence 38 months after the sling procedure. The authors concluded that patients with predominant urgency incontinence have poorer results than those with predominant stress incontinence.

In a retrospective evaluation of long-term effects of retropubic MUS on OAB and urodynamic SUI, Leron and colleagues (2009) noted 88.7% cure and 9% improvement with 62.2% improvement in OAB symptoms. There was no change in severity of symptoms in a third of the patients. De novo OAB symptoms developed in 6.2%.

Using the AUA Symptom Index for measurement of outcomes, Ballert and colleagues (2008) found no difference in storage,

voiding, or total score between patients with SUI and those with MUI or those undergoing retropubic versus transobturator MUS. Sinha and colleagues (2008) used the Medical, Epidemiologic, and Social Aspects of Ageing (MESA) questionnaire and other outcome measures used by the British Society of Urogynaecology (BSUG) database for short-term evaluation of the retropubic MUS in women with MUI. Stress and urgency incontinence were either cured or improved in 78% and 75% of women, respectively. The postoperative global impression of outcome noted great or moderate improvement in 75% of patients and reduction in mean MESA scores of 69% ($P < .001$).

Duckett and colleagues (2008) used perineal ultrasonography in 77 women with DO and urodynamic stress incontinence to determine whether the position of a retropubic MUS has any effect on the resolution of irritative symptoms. They found that placement of the sling on any part of the urethra is not more likely to resolve irritative bladder symptoms.

Three studies have attempted to correlate preoperative variables with outcomes of retropubic MUS procedures in women with MUI (Duckett and Basu, 2007; Gamble and colleagues, 2008; Panayi et al, 2009). Duckett and Basu (2007) reported on correlation between preoperative pressure-flow studies and resolution of DO and OAB symptoms after placement of a sling. Pressure-flow studies were compared before and after the placement of the sling. Women with a Qmax significantly decreased after the sling surgery were more likely to have persistent OAB symptoms. The flow rate was significantly higher in women before the sling placement with an objective cure of DO after surgery than in those with persistent DO. The researchers felt that this supported an obstructive cause in women with persistent DO.

In 2008, Gamble and colleagues found that age, nocturia, maximum capacity, and choice of sling procedure (lowest rate of DO with transobturator MUSs, followed by retropubic MUSs and then PVSs) affected the persistence of DO and UII. Panayi et al (2009) found higher median preoperative opening detrusor pressure in women with DO postoperatively (33 cm H₂O vs. 26 cm H₂O, $P < .05$) after MUS surgery.

Four groups have discussed treatment of MUI with a transobturator sling (Botros et al, 2007; Paick et al, 2008; Tahseen and Reid, 2009; Abdel-Fattah et al, 2014). Botros and colleagues (2007) compared the resolution of DO, UII, and de novo urgency among the Monarc (125), Gynecare TVT (99), and SPARC (52) procedures. De novo urgency was significantly lower in the Monarc group (8% vs. 33% with the Gynecare TVT and 17% with the SPARC, $P = .04$), yet rates of resolution of DO, UII, and de novo DO did not differ among the three groups. Paick and colleagues (2008) placed 72 Gynecare TVT, 22 SPARC, and 50 transobturator slings in women with MUI. There were no significant differences in SUI cure rates or general urinary incontinence cure rates among the three slings. The presence of DO during preoperative urodynamic studies was associated with a high treatment failure of UII in all three groups. Tahseen and Reid (2009) performed a transobturator MUS procedure in 58 women and found a 77% SUI cure rate and 19% SUI improvement rate. In addition, UII was cured in 43% and improved in 36% of women with MUI. Twenty-one percent had persistent UII.

Overall, although most studies have reported that patients with genuine SUI have a higher cure rate than patients with MUI, MUSs do appear to be an effective treatment for incontinence. In addition, several studies have demonstrated improvement in OAB symptoms and less need for anticholinergic medications in patients with MUI after MUS surgery.

Outcomes of Midurethral Slings for Intrinsic Sphincteric Deficiency

A deficient sphincter mechanism is an important risk factor for failure of conventional anti-incontinence procedures. It is difficult to evaluate the efficacy of surgical treatment for ISD because no universally accepted definition presently exists. However, as previously stated in the PVS section, ISD is often defined uroynamically

as a leak point pressure less than 60 cm H₂O or an MUCP less than 20 cm H₂O. What is clear from the current literature is that the success of MUSs is lower in patients with a fixed urethra (no urethral mobility) and low leak point pressures. In addition, a preoperatively fixed urethra seems to be more predictive of a worse outcome (no cure) than a low leak point pressure. Patients with fixed urethras have poor outcomes after MUS surgery regardless of leak point pressure.

In 2001, [Rezapour and colleagues](#) published a prospective 4-year follow-up study of 49 women with ISD who underwent retropubic MUS procedures. Forty-one of these women had hypermobility of the urethra; the other 8 had immobile urethras. Postoperatively, 36 (74%) of patients were cured and 12% were improved; in 7 patients (14%) the procedure failed. It is important to note that none of the women with fixed urethras were cured; only 3 improved, and in 5 the procedure failed. Other studies support lower cure rates of retropubic MUS in women with low leak point pressures when rates of urethral hypermobility (fixed vs. nonfixed urethras) are not statistically different ([Paick et al, 2004](#)). Urethral mobility before MUS procedures has been shown to be predictive of success. The more the proximal urethra moves during Valsalva maneuvers, the better the cure rate for incontinence ([Fritel et al, 2002](#)). Leak point pressures alone have not been shown to predict outcome after a MUS procedure ([Gutierrez Banos et al, 2004](#); [Rodriguez et al, 2004](#)); therefore, **low leak point pressures are not necessarily a contraindication to retropubic MUS surgery**. Leak point pressures in the era of the MUS should be correlated with the patient's physical examination and used to counsel patients about their risk for a reduced chance of success.

A few more recent studies have also been performed to assess the clinical effectiveness of the retropubic MUS procedure in women with ISD ([Ghezzi et al, 2006](#); [O'Connor et al, 2006](#); [Bai et al, 2007](#); [Rechberger et al, 2009](#)). In all of these studies, patients were included with urodynamic stress incontinence from ISD, based on a Valsalva leak point pressure (VLPP) below 60 cm H₂O. Ghezzi and colleagues (2006) prospectively studied 35 patients and noted a 93.7% cure rate at 12.5 months' follow-up. Two of the three patients in whom the procedure failed were noted to have a fixed urethra preoperatively. In a retrospective study, Bai compared the treatment outcomes of the retropubic MUSs in patients with ISD (31 patients) and non-ISD (80 patients) SUI after 1-year follow-up. Whereas the 1-month follow-up found significant difference in cure rates between the ISD (87%) and non-ISD patients (100%), by 1 year after surgery there was no significant difference ([Bai et al, 2007](#)). [Rechberger and colleagues \(2009\)](#) conducted a prospective, randomized trial with a follow-up of 18 months comparing the clinical effectiveness of retropubic and transobturator MUSs. Although the efficacy of both techniques was comparable, the retropubic route was more efficient in the ISD group ([Rechberger et al, 2009](#)).

For transobturator MUSs, [Delorme \(2001\)](#) noted that 15.6% of his patients had ISD, and [Mellier and colleagues \(2004\)](#) diagnosed 28% of their patients with ISD. Despite these diverse populations of patients, relatively similar results were obtained. O'Connor and colleagues were the first group to examine the early outcomes of the transobturator approach for SUI in women with variable VLPP. Patients were divided into high (>60 cm H₂O) and low (<60 cm H₂O) categories based on VLPP. The odds of continued SUI after transobturator MUS surgery were 12 times greater for women with VLPP below 60 cm H₂O compared with those with VLPP above 60 cm H₂O ([O'Connor et al, 2006](#)). In general, no preoperative predictors of outcomes using either clinical or urodynamic parameters have been established to determine overall results of MUS procedures.

Even though the 2010 [Richter and colleagues](#) study comparing retropubic and transobturator slings was not designed to look at ISD, all the patients underwent preoperative urodynamic studies. The authors found that VLPP and MUCP had no effect on the outcomes of the sling surgeries. However, the authors did not look at the effect of urethral hypermobility on outcomes.

Overall, clinical experience with the MUS operation suggests that it is beneficial in the management of stress incontinence in

patients with ISD as long as there is preoperative urethral mobility. In addition, the absolute reported rates of cure and improvement for patients with ISD are within the range of reported results experienced with other types of procedures.

Outcomes of Midurethral Slings for Recurrent Stress Urinary Incontinence

There are limited data specifically addressing the efficacy of MUS procedures as secondary surgery in women with recurrent incontinence. Several small studies with relatively short follow-up could be found addressing the issue ([Azam et al, 2001](#); [Rezapour and Ulmsten, 2001](#); [Kuuva and Nilsson, 2002](#); [Lo et al, 2002](#); [Rardin et al, 2002a](#); [Kuuva and Nilsson, 2003](#)). Comparison of these studies is hampered by differences in the definitions used for cure, improvement, and failure and the methods of evaluating outcomes (objective, subjective, or both). Also, the population of patients in most studies of recurrent SUI may be biased by the inclusion of women in whom bulking agents had failed. Despite these limitations, cure rates of MUS surgery after prior failed anti-incontinence surgery range from 81% to 89.6%. With further review of these articles, several trends emerge. The procedure can be performed in the same way as it is performed for primary SUI. The complication rate is similar to that of retropubic MUSs done for primary SUI, but the risk of bladder perforation appears to be higher in women who have had one or more prior retropubic suspensions. Also, as is the case with primary surgery, the failure rate is higher in women with immobile urethras.

One of the longest follow-ups of women who underwent retropubic MUS procedures for recurrent incontinence is 4 years in a study by [Rezapour and Ulmsten \(2001\)](#). The 34 women studied had undergone 64 different anti-incontinence surgeries. Any patient with significant prolapse, DO, or ISD defined as MUCP of less than 20 cm H₂O was excluded. By physical examination, 24 women had a hypermobile urethra. Ten had a less mobile urethra, but none had a fixed urethra. The procedure was performed using the standard MUS technique, and only one bladder perforation occurred in a patient with a prior Marshall-Marchetti-Krantz (MMK) urethroplasty. No significant complications were encountered. Twenty-eight (82%) were cured by objective and subjective parameters; 3 (9%) were improved based on failure to achieve more than 90% improvement in QoL; and in 3 the procedures were failures. Postoperative voiding dysfunction was negligible with no change in PVR urine after 8 weeks. Long-term catheterization was not necessary in any patient. These results were durable up to 5 years.

Only a few small series present the outcomes of patients treated with a repeat MUS for recurrent SUI ([Riachi et al, 2002](#); [Villet et al, 2002](#); [Lee et al, 2007a](#); [Tsivian et al, 2007](#); [Biggs et al, 2009](#)). In these studies, the cure rates for patients with recurrent SUI are higher for retropubic slings than for transobturator slings. Tsivian found that in 12 patients with repeat MUS surgeries, the only procedure that failed was the transobturator MUS placement ([Tsivian et al, 2007](#)). Similarly, Lee found that the cure rate for the repeat transobturator approach was 62.5% as compared with 92.3% for the repeat retropubic sling procedure ([Lee et al, 2007a](#)). A possible explanation for this difference is the angle of the sling; specifically, the retropubic sling has a U shape, which may be more supportive and obstructive than the transobturator MUS. In addition, the out-to-in approach to the transobturator procedure may require wider dissection of the periurethral area, leading to future migration of the sling. Salvage procedures are performed in some women in whom the initial MUS failed because of underlying ISD or who now have a fixed urethra from the initial surgery. This is consistent with the evidence of high success with retropubic slings for patients with a component of ISD.

In 2010, [Stav and colleagues](#) reported the results of a retrospective analysis of outcomes in 1035 women after primary MUS surgery and 75 women after repeat MUS surgery ([Stav et al, 2010a](#)). The authors found that repeat MUS surgery was significantly less effective at curing incontinence than a primary sling (62% vs. 86%,

$P < .001$). The rates of complications were similar between the two groups; however, the repeat group had a significantly higher rate of de novo urgency and de novo urgency incontinence. All of the patients underwent preoperative urodynamic studies, and the rate of preoperative MUI was similar between the two groups. It is interesting to note that the rate of ISD was significantly higher in the repeat group preoperatively (31% vs. 13%, $P < .001$).

In 2013, [Agur and colleagues](#) performed a meta-analysis of the 10 randomized, controlled trials of MUSs that addressed recurrent SUI. The review included 350 women with a mean follow-up of 18.1 months. The authors found no significant difference in subjective cure rates in patients after retropubic versus transobturator MUS surgery.

KEY POINTS: MIDURETHRAL SLINGS FOR RECURRENT STRESS URINARY INCONTINENCE

- A repeat midurethral synthetic sling procedure for persistent or recurrent SUI is a viable option for select patients in whom the initial procedure has failed.
- Some studies show cure rates to be higher for retropubic slings than for transobturator slings. This may be the result of unequal rates of ISD in different study populations.

Outcomes of Midurethral Slings in Patients with Pelvic Organ Prolapse

A large proportion of women with stress incontinence have associated pelvic organ prolapse. Many studies have explored the outcomes of MUS surgery with concomitant pelvic organ prolapse surgery. The advantage of using a synthetic sling concomitantly with pelvic organ prolapse repair is that operative time is reduced and blood loss from the MUS portion is minimal compared with placement of autologous slings or retropubic suspensions. **Some of the theoretic risks of MUSs with concomitant transvaginal surgery are that the increased dissection will increase exposure of the graft, leading to greater rates of infection, perforation, or vaginal exposure, or that increased blood loss or anatomic distortion from the concomitant procedures could increase the rate of sling migration and postoperative voiding dysfunction or obstruction.**

Although most studies tend to be small and have short follow-up, **results suggest that the MUS can be added to prolapse surgery with minimal morbidity.** Success rates in combined MUS and prolapse repair vary from 72.7% to 93% ([Jomaa, 2001](#); [Huang et al, 2003](#); [Meltomaa et al, 2004](#); [Wei et al, 2012](#)). Even in questionnaire-based assessments 3 years after surgery, the data do not show a statistical difference in the cure rate of SUI and incidence of urgency symptoms after MUS surgery alone or in combination with other vaginal surgery ([Meltomaa et al, 2004](#)). However, transient urinary retention occurred more often in patients undergoing concomitant vaginal surgery, but urethrolysis rates were low and not statistically different between groups. Interpretations of rates of postoperative urinary retention are limited by variation in the definition of retention, and therefore caution must be exercised when reviewing outcomes.

[Gordon and colleagues \(2005\)](#) examined retropubic MUS surgery as a prophylactic procedure for stress incontinence in prolapse repairs. None of the patients had undergone prior incontinence surgery. With a mean follow-up of 14 months, no patient developed symptomatic stress incontinence, but 3 had a positive stress test result urodynamically. Six of 9 patients with preoperative urgency had persistent symptoms, and 4 (13.3%) developed de novo urgency without evidence of obstruction. No woman had urinary retention lasting more than 2 weeks.

Five-year data from a prospective analysis of a large group of women undergoing MUS surgery for occult stress incontinence combined with transvaginal repair of second- or third-degree prolapse showed a low incidence of complications ([Groutz et al, 2004](#)). The authors reported that 1 case of bladder perforation was managed conservatively without consequence. Two patients experienced extended voiding difficulty requiring catheterization for more than 7 days, but urethrolysis was not necessary in any case. Three cases of vaginal erosion were documented. Two patients developed recurrent symptomatic stress incontinence, and another 15 patients were found to have asymptomatic, urodynamically confirmed stress incontinence. Eight patients developed de novo urgency incontinence, and 72% of the 18 patients with preoperative urgency incontinence had postoperative persistent incontinence. The Cochrane Incontinence Group reviewed 22 randomized trials of surgical prolapse repair including 2368 women. They concluded that the addition of a retropubic MUS to endopelvic fascial plication, Burch colposuspension, and abdominal sacrocolpopexy may reduce the incidence of postoperative SUI, but issues of cost and associated adverse effects were unclear ([Maher et al, 2008](#)).

Although concurrent surgery does not appear to alter success of MUS, whether concurrent surgery alters the time to efficient voiding or incidence of urinary retention was examined separately in a retrospective study of 267 women (66% having concurrent prolapse repair) by [Sokol and colleagues \(2005\)](#). The authors noted that there was no significant difference in median days to voiding and rate of urinary retention based on prolapse repair status. However, increasing age, decreasing BMI, and postoperative UTI were independent predictors of time to adequate voiding. Only a previous history of incontinence surgery was an independent predictor of urinary retention. No statistically significant difference in the rate of urethrolysis between MUS alone and MUS with prolapse repair was found.

Unlike most other authors, [Partoll \(2002\)](#) claimed that urinary retention is far more common after combined procedures than MUS placement alone. Results showed a 94% cure rate at 11 months and an alarming 43% rate of urinary retention after concurrent anterior or posterior repair. However, in her study, urinary retention was defined as not meeting the criteria for catheter removal on postoperative day 2. The expectation of voiding efficiently within 48 hours of surgery, rather than the more lenient expectations in other studies, probably accounts for the higher rate of retention found in her study. Using Medicare claims data on a 5% national random sample of female beneficiaries who underwent sling procedures, [Anger and colleagues \(2008\)](#) reviewed 1356 sling cases. Of these, 467 (34.4%) included concomitant prolapse repairs. Women who underwent prolapse repair at the time of the sling surgery were significantly more likely to be diagnosed with postoperative outlet obstruction (9.4% vs. 5.5%, $P < .007$), but less likely to undergo a repeat procedure for stress incontinence or reoperation for prolapse within 1 year after sling surgery.

When MUSs are placed for urodynamic or occult SUI at time of prolapse repair, the risk of intervention because of obstruction is equivalent to the risk of intervention for SUI if no MUS was placed (8.5% and 8.3%, respectively) ([Ballert et al, 2009](#)). Also, the risk of intervention for stress incontinence in patients with clinical stress incontinence but no urodynamic or occult SUI and no MUS was 30%.

MUSs placed with either transvaginal or laparoscopic-assisted vaginal hysterectomy and anterior or posterior colporrhaphy have been shown to have success rates similar to those in published series of MUS surgery alone ([Huang et al, 2005](#)). Complication rates are also in accordance with other MUS series, with 2% bladder trocar injury, 11% postoperative urgency, and 11% postoperative voiding difficulty. A study specifically looking at the complications and cure rates of MUS performed with or without vaginal hysterectomy found that there was no overall difference ([Darai et al, 2002](#)). The MUS-hysterectomy group did have a trend toward more bladder perforation and lower postoperative urinary flow rates, but it was not statistically significant. Objective and subjective cures for this

group were 92.5% and 75%, respectively, which was not significantly different from the MUS-alone group.

In 2007, [Anger and colleagues](#) evaluated the relationship between provider specialty and outcomes of sling surgery, specifically related to concurrent prolapse management ([Anger et al, 2007b](#)). Using 1999 to 2000 Medicare data, the researchers found that 1063 sling procedures were performed by urologists, and gynecologists performed 246. Urologists performed concomitant prolapse repairs in 29.1% of cases versus 55.7% among gynecologists ($P < .0001$). Postoperatively, urologists were more likely to perform a repeat incontinence procedure (9.3% vs. 4.9%, $P = .024$) and prolapse repair (26.0% vs. 12.2%, $P < .0001$). These findings suggest that urologists should identify and manage prolapse at the time of evaluation of urinary incontinence to avoid the morbidity and cost of repeat surgery.

In 2012, Wei and colleagues presented their results of the Outcomes Following Vaginal Prolapse Repair and Midurethral Sling (OPUS) trial. This trial attempted to determine whether the use of a concomitant prophylactic anti-incontinence procedure (retropubic MUS) prevents the development of SUI in women undergoing prolapse surgery, and to evaluate the cost-effectiveness of this prophylactic approach. A sham incision was used in the control arm. A total of 327 women (no preoperative incontinence) completed follow-up at 1 year; the rate of patients with objective or subjective urinary incontinence was significantly higher in the sham group versus the MUS group (43.0% vs. 27.3%). The rates of trocar bladder injury, UTI, and bleeding, although low, were all significantly higher in the MUS group. It is our opinion that placement of a prophylactic MUS at the time of prolapse surgery should be performed only after thorough preoperative counseling regarding patient expectations and goals.

Outcomes of Midurethral Slings in Elderly Patients

Although there is a large body of literature that demonstrates the efficacy and low morbidity of MUSs, there is a paucity of data evaluating the effect of advanced age on outcomes. Aging affects the lower urinary tract both anatomically and functionally. The aging lower urinary tract has a higher rate of DO, urgency incontinence, and ISD. Emptying abnormalities related to impaired contractility are also more common in elderly persons. Older women are more likely to have had prior procedures for incontinence and therefore may have higher rates of urethral fixation. More severe vaginal atrophy related to long-standing lack of salubrious estrogen support of the vaginal tissues in the older woman could pose a greater risk of poor healing and exposure after vaginal incontinence surgery. In addition, older patients are generally considered poorer surgical candidates because of medical comorbidities that could complicate the surgery, the surgical outcome, or the postoperative course.

A few studies with relatively small numbers of patients have examined the safety and efficacy of MUSs in older women. In all these studies, "old" was defined as 70 years and older. The most robust of the studies was a prospective comparison of 460 consecutive women who underwent MUS surgery with a mean follow-up of 26 months by [Gordon and colleagues \(2005\)](#). In that study, 157 (34%) were elderly, and all women underwent urodynamic evaluations preoperatively and 3 months postoperatively. Preoperatively, a statistically significant greater prevalence of mixed incontinence was noted in the older (31%) versus younger (23%) patients. Intraoperative complications were infrequent, although there were significantly fewer bladder trocar injuries in the elderly population. The incidence of postoperative fever, UTI, wound infection, and hematoma formation was similar in the two groups. Older patients did experience some age-related morbidities such as pulmonary embolism (2), cardiac arrhythmia (2), DVT (1), and pneumonia (1), whereas younger patients had only 1 case of cardiac arrhythmia. Older women experienced no increased risk of vaginal exposure. The rates of postoperative voiding dysfunction necessitating catheterization for more than 1 week were low and similar between groups. Cure rates were similar between the elderly and

young patients (93% and 94%, respectively). Rates of urgency incontinence were similar between groups, but the rate of de novo urgency incontinence was significantly greater in the older patients (18% vs. 4%).

A similar rate of postoperative de novo urgency incontinence (18.4%) in elderly women undergoing MUS surgery was documented in a smaller study of 76 women ([Sevestre et al, 2003](#)). One strength of this study is that a description of the degree of urethral hypermobility was given. Of these women, 53% had urethral hypermobility defined by Q-tip test greater than 30 degrees, 28.9% had undergone prior incontinence procedures, and 4 (5.3%) showed urodynamic evidence of DO. At a mean follow-up of 24.6 months, 67% of the patients were cured as determined by questionnaire and examination. Ten procedures (13.2%) failed, and all of these patients had negative Q-tip tests preoperatively. Satisfaction with the procedure was 82%, and rates of dissatisfaction were higher in those with de novo urgency incontinence. For the older women with a negative Q-tip test, the cure rate was 71%, compared with 100% in women with a positive Q-tip test. The rate of immediate urinary retention was 26.3%, but only 1 patient had urinary retention for more than 1 week.

[Liapis and colleagues \(2006\)](#) also correlated the degree of urethral hypermobility and outcomes of MUS surgery in women aged 65 to 85 years. An overall cure rate of 76% was reported, with positive correlation to bladder neck mobility. In patients in whom the angle of displacement on the Q-tip test was less than 30 degrees, 42% became continent, whereas 90% were continent among those with an angle greater than 30 degrees. Among those in whom the angle was less than 10 degrees, 80% remained incontinent.

The success rates and complications after Burch colposuspension and MUS were compared in women over 70 years versus younger women ([Pugsley et al, 2005](#)). The cure rates were similar between the age groups. There was an increased incidence of UTI in the elderly Burch colposuspension and MUS patients. Women over 70 years required more long-term self-catheterization in the Burch colposuspension group.

The cure rates in older women with urethral hypermobility are comparable to those in younger women. Complication rates vary, with some studies citing a higher rate of age-related morbidities but no apparent increase in intraoperative complications. [Jha and colleagues \(2009\)](#) evaluated factors influencing outcome with retropubic MUSs and found that age did not significantly affect outcomes for stress incontinence reduction or improvement in QoL. Postoperative voiding dysfunction or increased de novo urgency do seem to be complications of greater incidence and significant impact in older women. Postoperative urgency symptoms in as many as 60% of women older than 70 years have been reported ([Allahdin et al, 2004](#)), and 44% developed the symptom de novo. [Bafghi and colleagues \(2005\)](#) noted cure rates among patients younger than 70 years of 97.5% versus 78.5% among patients older than 70 years ($P = .001$). The satisfaction among the younger group was also higher than in the older group: 92.6% and 66.7%, respectively. This difference was attributed to higher rates of de novo and persistent urgency incontinence in the over-75 years age group.

Another important measure of the success of the MUS in elderly patients is QoL assessments. The outcome of MUS surgery was assessed prospectively in older women at a mean follow-up of 22 months by a validated health-related QoL instrument, the King's Health Questionnaire ([Walsh et al, 2004](#)). The improvement in stress incontinence was greater in the age group younger than 70, which is not clearly attributed to any preoperative factor. Rates of preoperative DO were 24% versus 9% in older and younger women, respectively. Older women had a history of prior surgery more often than younger women (67% vs. 28%) and lower leak point pressures, but no specific comment on their physical examination findings and degree of urethral hypermobility was made. Although the outcome of MUS surgery was successful, the hospital course may be longer, as found by [Walsh and colleagues \(2004\)](#). The mean hospital stay in their series was 6 days, indicating that the postoperative morbidity in this age group was significant. The reasons for

the longer hospital stays were not given in this study. [Campeau and colleagues \(2007\)](#) compared elderly women who either underwent a Gynecare TVT procedure or had to wait 6 months for surgery, using QoL questionnaires. The women who underwent surgery had a significantly higher QoL ($P < .0001$), yet 22.6% experienced bladder perforation and 12.9% urinary retention.

[Hellberg and colleagues \(2007\)](#) used a mailed questionnaire for 970 consecutive MUS procedures performed from 1995 to 2001, to compare outcomes between women older than 75 years and younger women at a mean follow-up of 5.7 years. The older women were significantly more often on hormone replacement therapy, had lower education, and had a history of recurrent urinary infections, previous vaginal repair, and previous incontinence surgery. The elderly patients more commonly had mixed incontinence and required longer hospitalization postoperatively. The unfavorable cure rate among the older women (55.7% vs. 79.7%, $P = .0001$) was a result of a higher failure rate for stress incontinence rather than for urgency symptoms.

A multicenter, prospective randomized clinical trial was performed to compare MUS surgery versus no treatment in elderly women with SUI ([Campeau et al, 2007](#)). Campeau studied 69 women over the age of 70 years who consented to be randomized to undergo immediate MUS surgery or wait for 6 months before submitting to the same surgery (control group). The main outcomes measured included the I-QOL questionnaire, the Patient Satisfaction Questionnaire, and the Urinary Problems Self-Assessment Questionnaire. At 6 months after randomization, the group of elderly women who underwent immediate MUS surgery had significant improvement in QoL and patient satisfaction and fewer urinary concerns compared with the group of women waiting for the same surgery. It is important to note that no age-related morbidity was observed in the immediate surgery group.

Possibly because of preoperative factors such as MUI or even decreased urethral hypermobility, the rate of persistent SUI after retropubic or transobturator MUS procedures appears higher in the elderly population. In addition, the elderly population has a higher incidence of de novo urgency and urgency incontinence after MUS surgery. Also, although there may be some initial increase in perioperative morbidity in the elderly population, MUS surgery does appear to be safe. Lastly, while the literature is insufficient to support one anti-incontinence surgical procedure over another for the elderly woman, it can be concluded that **elderly women should not be excluded from potentially curative MUS surgery based on their age alone.**

Outcomes of Midurethral Slings in Obese Patients

Whether obesity affects surgical outcome with MUSs is controversial. Several studies have examined the safety and efficacy of MUS surgery in this population. In a prospective study of 242 women with SUI, women were stratified into three groups on the basis of BMI ([Mukherjee and Constantine, 2001](#)). The cure rate in obese women was 90% versus 95% in women with a BMI of 25 to 29 and 85% in those with a BMI less than 25. No women experienced a wound infection, and there was no higher rate of retropubic hematoma in obese women. In addition, obese patients undergoing MUS surgery did not demonstrate a statistically significant difference in the incidence of voiding dysfunction (de novo urgency symptoms, urgency incontinence, or voiding disorders).

Although few in number, studies with 6 to 12 months of follow-up support equal efficacy and no difference in postoperative complication rates. [Skriapas and colleagues \(2006\)](#) matched 31 women with BMI above 40 with 52 women with BMI below 30 and reported on their 18.5-month follow-up after MUS surgery. The continence rates among the morbidly obese group were not significantly different from the control group, 87% and 92% ($P = .0103$), respectively. The early postoperative complications were significantly higher among the morbidly obese patients. [Killingsworth and colleagues \(2009\)](#) reported on 127 overweight to obese women and concluded that success rates, patient satisfaction, and complications were not significantly different with increasing BMI. [Meschia](#)

[and colleagues \(2007\)](#) had similar findings to [Mukherjee and Constantine \(2001\)](#) and [Killingsworth and colleagues \(2009\)](#), with no differences in BMI of successes and failure, suggesting that MUS surgery could be confidently used in overweight women. [Muller and colleagues \(2007\)](#) reviewed randomized and retrospective clinical trials in the English MUS surgery literature from 1998 to 2006. Neither age over 70 years nor morbid obesity was a risk factor for failure of the MUS; however, there was an increase in de novo urgency among the elderly women and those with a BMI over 35.

[Hellberg and colleagues \(2007\)](#) conducted a questionnaire-based study including 970 consecutive MUS procedures performed from 1995 to 2001 to compare outcomes between women with a BMI above 35 ($n = 61$) and those who had normal weight at a mean follow-up of 5.7 years. There was a sharp decline in long-term cure rates between women with BMI below 25 and those above 35: 81.2% and 52.1%, $P < .001$. The obese women were significantly older, had a higher parity, were less educated, and more often had diabetes and chronic bronchitis. The women with normal weight had higher mean PVR volume postoperatively and required more adjustments of sling. The increased failure rate among the obese population was a result of low cure rates of both stress and urgency components.

Contrary to the findings of earlier studies by [Lovatsis and colleagues \(2003\)](#) and [Rafi and colleagues \(2003\)](#), [Stav and colleagues \(2010b\)](#) and [Greer and colleagues \(2008\)](#) found a higher rate of bladder trocar injury in nonobese patients during MUS surgery. **Overall, the rate of complications appears to be similar in obese versus nonobese patients undergoing MUS surgery.** In a review of the literature, only a retrospective study of 742 women (247 obese) undergoing vaginal surgery (55% MUS surgery) by [Chen and colleagues \(2007\)](#) showed a significantly higher rate of complications in obese patients (operative site wound infection: 7% vs. 2%, $P = .01$).

In further assessing the literature, most studies have consistently shown a lower cure rate in obese patients after MUS surgery, but only 3 of 16 studies showed a statistically significant worse outcome in obese patients. All 3 of those studies defined outcomes subjectively only. The largest of those series was a retrospective study by [Stav and colleagues \(2010b\)](#) of 741 obese (BMI above 25) and 371 nonobese women. The cure rate measured by validated questionnaires was significantly lower in the obese population (80% vs. 90%) at a mean follow-up of 50 months. Overall, although there is no definitive prospective randomized trial, it does appear that there is a consistently lower cure rate in obese women. However, MUSs are still an effective treatment in this patient population with relatively low morbidity. [Table 84-12](#) contains a review of the current literature.

KEY POINTS: MIDURETHRAL SLING SURGERY OUTCOMES IN PATIENTS WITH CONCOMITANT PROLAPSE REPAIR AND IN ELDERLY AND OBESE PATIENTS

- The literature supports the use of MUSs in a variety of special populations of patients. Efficacy and safety of MUSs are not compromised in the elderly, the obese, or those undergoing concomitant vaginal surgery.
- A few small studies suggest that concomitant vaginal surgery places a patient at higher risk for delayed return to normal voiding and urinary retention. However, limitations in the studies prevent comparison of the data.
- It is difficult to analyze the current sling data because of the lack of standard definitions of cure and improvement and lack of standard outcome measures.
- Absolute conclusions about the use of MUSs in special populations should not be made until larger prospective multicenter studies have been performed.

Complications of Retropubic, Transobturator and Single-Incision Midurethral Slings

Over the past 10 years there has been a 27% increase in the rate of surgery for SUI, and a large portion of that increase is a result of the growing popularity of the MUS (Jonsson et al, 2012). However, in 2010 the FDA released a revised statement alerting the public to safety concerns regarding the use of synthetic mesh for pelvic organ prolapse and SUI surgery (U.S. Food and Drug Administration, 2010). The FDA became aware of problems related to synthetic mesh because of information contained in the Manufacturer and User Facility Device Experience (MAUDE) database. According to MAUDE data, from 2008 to 2010 there were 1371 voluntary and involuntary self-reported medical device reports of complications related to MUSs, and a significant portion of those were mesh perforation and exposure (U.S. Food and Drug Administration, 2011).

In general, complications associated with retropubic, transobturator, and single-incision MUSs appear to be within the acceptable range for incontinence procedures. However, it is important to remember that QoL is affected not only by the outcome of the incontinence surgery from the standpoint of cure or improvement but also by the appearance of voiding difficulties, UTIs, and other adverse consequences of the surgical procedure itself. The Finnish MUS registry demonstrated a pronounced learning curve for surgeons adopting the new MUS technology (Kuuva and Nilsson, 2003). This registry is unique in that all of the nation's MUS procedures are recorded in this data bank and therefore the results are reflective of the entire national experience with this new procedure. Another registry is also maintained in Austria and includes over 5000 cases, but it does not involve all surgeons in the country (Tamussino et al, 2001). Overall, the rate of complications associated with the MUS procedure is relatively low. The rates of bladder trocar injury in the two aforementioned national registries were 2.7% and 3.8%. The rates of voiding dysfunction and wound healing problems were 7.6% and 1%, respectively. A more comprehensive look at complications in randomized prospective trials and large retrospective studies is presented in Table 84-13 on the Expert Consult website.

As previously mentioned, the term *perforation* means that the polypropylene mesh has either entered the urinary tract (urethra, bladder, or ureters) or has penetrated bowel. The term *exposure* of mesh refers to the occurrence of visible or palpable mesh in the vagina or skin that is not covered by overlying tissue. For the purposes of this discussion, *trocar injury* refers to the passage of the trocar into the urethra or bladder at the time of sling placement.

The exact cause of these complications is debatable, but they likely arise from a combination of patient and technical factors. These factors include patient body habitus, subclinical infection, poor tissue ingrowth into the sling, disturbed wound healing, rolling or twisting of the sling, excessive friction between host tissue and the sling, sling material properties, and iatrogenic injury and surgeon technical error (Kobashi and Govier, 2003; Domingo et al, 2005; Stav et al, 2010b). Biomechanical properties of the sling material have also been shown to play a major role in the incidence of complications related to mesh exposure. Although various materials have been historically used for sling implants, there has been a trend in the contemporary literature toward the use of macroporous polypropylene slings. The increased pore size of these materials allows for excellent tissue ingrowth, promotes integration with the surrounding host tissues, and decreases encapsulation and infection (Dietz et al, 2001, 2003; Slack et al, 2005). Adherence to meticulous surgical technique and use of polypropylene mesh with favorable biomechanical properties should help the surgeon minimize complications.

Midurethral Sling Mesh Exposure

Vaginal mesh exposure is a rare complication after the MUS procedure (Fig. 84-12). In a review of prospective trials and large retrospective studies of MUS outcomes, the rate of vaginal mesh exposure was 0.5% to 8.1% (see Table 84-13 on the Expert Consult

Figure 84-12. Vaginal mesh exposure.

website). Most cases of vaginal mesh exposure manifest within a few weeks to a few months after the MUS procedure. Symptoms of vaginal exposure include vaginal discharge (with variable constituents and different amounts of blood and inflammatory components), a palpable rough surface in the vagina, sexual discomfort (including partner related), pelvic pain, inguinal discomfort, and lower urinary tract symptoms (urgency, frequency, persistent incontinence, hematuria). Symptoms are often nonspecific, and therefore a high index of suspicion is required. In cases of mesh exposure, careful vaginal examination usually identifies an area on the anterior vaginal wall with separated epithelial edges and visible mesh. The management of this complication is not standardized, and there are various reports claiming successful outcomes with observation, partial sling excision, complete sling excision, and reapproximation of the vaginal mucosa over the exposed mesh (Table 84-14).

It appears that the material composition of mesh is particularly important in the event of mesh exposure. Domingo and colleagues (2005) reported a relatively high incidence of vaginal exposure in their series using either the ObTape or UraTape. They attributed their exposure rate to the characteristics of the particular mesh that they used, with the reduced pore size and other mechanical properties of that particular material. They noted a slightly increased risk of exposure with the ObTape, 19% versus 12% compared with the UraTape, and they felt that this was most likely because of reduction in pore size and a higher degree of encapsulation. They also concluded that synthetic mesh with larger pore sizes facilitates vascular and tissue ingrowth, optimizing mesh incorporation. In this series, sling exposure was usually managed by removal through the transvaginal approach alone or combined with the transobturator approach. They noted continence rates of 78% (despite mesh removal in their series). Other authors have also reported a high rate of vaginal exposure of up to 15% after ObTape or UraTape MUS surgery (Babalola et al, 2005; Domingo et al, 2005; Deval et al, 2006; Al-Singary et al, 2007; Dobson et al, 2007; Giberti et al, 2007; Juma and Brito, 2007; Karsenty et al, 2007).

Australasian data on exposures presented by Hammad and colleagues (2005) included 17 vaginal exposures. Thirty-five percent of the exposures were asymptomatic and identified by vaginal examination. Symptomatic patients reported palpable mesh, vaginal discharge, local pain, UTI, and dyspareunia.

Newer, macroporous polypropylene slings have a much lower incidence of exposure and infectious complications (Neuman, 2007; Waltregny et al, 2008; Lee et al, 2009; Rechberger et al, 2009). Of the 197 women who underwent placement of multifilament transobturator slings by Rechberger and colleagues (2009), 2.5% developed vaginal exposures. Two groups reported no evidence of mesh exposure at 1-year (Lee et al, 2009) and 3-year (Waltregny et al, 2008) follow-up. Waltregny and colleagues (2008) reported 1

intraoperative vaginal sulcus laceration, which was closed uneventfully. Lee and colleagues (2009) proposed that a modified canal transobturator sling (creating a suburethral tunnel between two oblique lateral incisions in the anterior vaginal wall) decreases the incidence of vaginal exposure compared with the classic single midline incision. The value of this technique needs to be confirmed by a randomized control trial.

Chen and colleagues (2008) analyzed risk factors associated with vaginal exposure (6 of 239 patients, 2.5%) after synthetic sling placement. Women with diabetes were 8.3 times more at risk of developing vaginal exposure after synthetic sling placement. The vaginal exposure-free rate during the 24-month follow-up increased significantly in women with diabetes and type III multifilamentous polypropylene slings (intravaginal slingplasty). These authors encourage counseling women with diabetes of the risk of exposure.

Management of Midurethral Sling Mesh Exposure. Management of mesh exposure is within the scope of practice of most pelvic surgeons; however, mesh perforation of the bladder or urethra may require a tertiary referral. Some authors propose observing any exposure of mesh that is less than 1 cm because the area may heal spontaneously with mixed results (Kobashi and Govier, 2003; Tijdink et al, 2011). In the Kobashi and Govier study,

one Gynecare TVT and three SPARC patients with vaginal exposure were treated in a conservative fashion. All patients were observed with serial physical examinations and all patients had spontaneous re-epithelialization of the mesh at 3 months. The authors attributed their success to the macroporous characteristics of the polypropylene mesh, which facilitated excellent tissue ingrowth. Conservative management is less likely to be successful with older, less used sling materials such as Gore-Tex, polyethylene terephthalate, and silicone (Kobashi et al, 1999). In general, small areas of mesh exposure should be treated with sequentially increasing invasiveness. The first treatment should involve observation and then the addition of conjugated estrogen and possibly antibiotic creams. The next step should be limited excision and trimming with vaginal closure. If these options fail, excision of most of the mesh from a transvaginal approach should be pursued in most cases. Table 84-14 reviews the management of mesh exposure in the literature.

In a review by Huang and colleagues (2005), six vaginal exposures and one bladder perforation after polypropylene synthetic sling placement were initially expectantly managed. In four patients with vaginal mesh exposure of less than 1 cm, conservative management was initiated for a 3-month period. One of these patients was observed for 24 months without adverse sequelae. In contrast with the results seen by Kobashi and Govier (2003), none of the patients

in this review had vaginal epithelialization over the area of exposure. Therefore, all six patients underwent transvaginal mesh excision in conjunction with an excision of all fibrotic vaginal tissue. Symptoms resolved in all patients, and all patients were continent at their last follow-up. Although all patients ultimately required surgical intervention, the authors felt that a trial of conservative management in appropriately selected patients (i.e., exposure less than 1 cm) was reasonable, and that if no epithelialization occurs at 3 months of follow-up, the mesh should be surgically removed.

Depending on the preference of the surgeon and the size of the exposure, if conservative measures fail, the next step for intervention should be operative management. In the series reported on by [Tijdkink and colleagues \(2011\)](#), of 48 patients with mesh exposure, only 6 had persistent exposure after partial mesh excision. **Operative management typically involves excision of the exposed mesh, thorough irrigation with antibiotic solution, and closure of vaginal flaps.** The addition of topical antibiotics and conjugated estrogen cream may theoretically improve tissue quality before surgical intervention.

In a review of mesh-related complications in a series of 200 patients, [Tsivian and coworkers \(2004\)](#) observed five vaginal sling exposures. Four patients required surgical excision of the exposed mesh, and one asymptomatic patient was being observed conservatively without adverse outcomes. Exposure resolved in all patients after partial mesh excision and judicious vaginal debridement.

In the Finish nationwide review of 1455 MUS procedures, 10 patients were identified with vaginal polypropylene sling exposure. Three of these patients were managed without surgical intervention with good results and maintenance of continence ([Kuuva and Nilsson, 2002](#)). Four patients had the vaginal mucosa resutured over the exposed mesh, and two patients required partial mesh excision. One patient was lost to follow-up and management was unknown at the time of their report. According to this national registry, continence was maintained in all patients, regardless of the management.

Among 166 MUS surgeries performed by [Giri and colleagues \(2007\)](#), 5 patients (3%) developed vaginal exposure 4 to 40 months postoperatively. Patients reported vaginal discharge, pain, bleeding, and dyspareunia. In the operating room, the eroded margin of vaginal mucosa was trimmed and closed over the mesh. All of the patients were subsequently symptom free at 12-month follow-up.

[Ordorica and colleagues \(2008\)](#) reported on 11 vaginal exposures after nonautologous sling placement (33 retropubic, 2 bone anchors, 3 transobturator tape). In all cases, involved sling and suture were excised. The bone anchors were unable to be removed. An autologous sling was placed in the same setting if the patient complained of SUI at presentation. Two patients had recurrent or persistent SUI, 2 had de novo urgency or frequency, and 1 developed osteitis pubis.

The sexual function of women after correction of exposure from a MUS was determined using a validated questionnaire (Female Sexual Function Index [FSFI]) by [Kuhn and colleagues \(2009b\)](#). Among 21 exposures, 3 healed with topical estrogen and 18 patients with larger defects required operative intervention. Initially, vaginal closure was attempted, but 2 patients had recurrent exposure. One patient had repeat vaginal closure, and the other had partial sling excision and vaginal closure. The domains of desire, arousal, lubrication, satisfaction, and pain improved significantly. Orgasm remained unchanged.

Midurethral Sling Trocar Injury to the Urinary Tract

In most studies in the literature, results listed for perforation (or injury) of the bladder or urethra refer to trocar passage into the urinary tract at the time of surgery. In these studies, the trocar injury is recognized at the time of surgery and the trocar is passed again and the surgical case is continued. Trocar injury is generally thought of as a benign condition, and no study has shown a link between trocar injury and perioperative hemorrhage, hematomas, or subsequent mesh perforation of the bladder or urethra. Because of the nature of trocar passage, the rate of trocar injury is

KEY POINTS: MIDURETHRAL SLING MESH EXPOSURE

- Conservative management seems to be a plausible option in well-selected patients who are relatively asymptomatic and have small-caliber exposures (<1 cm). Good results have also been observed in selected patients with vaginal advancement flaps and suture approximation of the debrided vaginal mucosa over the exposed mesh.
- Even with partial excision of the mesh, continence is maintained in the majority of patients.
- Observation should never be considered when there is urethral or intravesical perforation. More data supporting specific management strategies are necessary before a given approach can be advocated for patients with this complication.
- We recommend initial judicious observation for small vaginal exposures (with use of topical conjugated estrogen cream when appropriate). Excision should be reserved for failure of conservative therapy or when local symptoms mitigate against observational management (e.g., bothersome dyspareunia).

generally lower with transobturator versus retropubic MUSs. The rate of bladder or urethral trocar injury at the time of retropubic MUS surgery in randomized trials falls between 2.7% and 23.8% ([Andonian et al, 2005](#); [Porena et al, 2007](#)).

Although initial reports described the risk with the transobturator MUS approach as being negligible, the rate of bladder or urethral trocar injury at the time of transobturator MUS surgery in randomized studies falls between 0% and 1.3% ([Porena et al, 2007](#); [Richter et al, 2010](#)) (see [Table 84-13](#) on the Expert Consult website). In 2004, [Minaglia and colleagues \(2004\)](#) reported three cases of intraoperative bladder injury while performing the transobturator insertion method. They identified all injuries intraoperatively because of their use of cystoscopy as an adjunct to all insertion procedures. All injuries were managed with catheter placement for 1 week postoperatively, and these authors noted no complications after sling removal and reinsertion at that same setting. It is possible that bladder trocar injuries are more likely to occur with out-to-in transobturator slings. With 10 of 11 bladder injuries occurring with the out-to-in technique in their study, [Tamussino and colleagues \(2007\)](#) concluded that trocar injury was more likely with this method.

Midurethral Sling Mesh Perforation of the Urethra

Urethral mesh perforation is defined as presence of sling material within the urethral lumen ([Fig. 84-13](#)). The incidence of urethral

Figure 84-13. Urethral mesh perforation and urethrovaginal fistula.

perforation following MUS (transobturator and retropubic) surgery was 0% to 0.6% in a review of randomized prospective and large retrospective studies (see Table 84-13 on the Expert Consult website). Factors thought to contribute to urethral perforation include compromised urethral blood supply (e.g., from radiation therapy or estrogen deficiency), excessive sling tension, extensive dissection too close to the urethra with subsequent urethral devascularization, iatrogenic urethral injury (at time of device insertion), and traumatic urethral dilation. Furthermore, twisting or rolling of the sling can create a ridge that leads to pressure necrosis and perforation through the urethra (Dell and O'Kelley, 2005). Management of this complication is extremely challenging with the possibility of significant morbidity, because access to the sling is traditionally gained by incising the urethra, although endoscopic management has been attempted.

Presenting symptoms are variable. In almost all published cases, voiding dysfunction is predominant, with typical symptoms including urgency, urgency incontinence, obstructive voiding, urinary retention, history of self-catheterization, urethral dilations, recurrent UTI, and persistent urinary incontinence (Haferkamp et al, 2002; Madjar et al, 2002; Pit, 2002; Sweat et al, 2002; Lieb and Das, 2003; Vassallo et al, 2003; Glavind and Sander, 2004; McLennan, 2004; Tsivian et al, 2004; Wai et al, 2004). Diagnosis is often delayed in these patients for an extended period of time. In a review by Amundsen and colleagues (2003), the average time from placement of the initial PVS to diagnosis of urethral perforation was 9 months.

Confirming the presence of the mesh within the urethral lumen during cystoscopy makes diagnosis. Voiding cystourethrography has also been useful adjunctively by documenting a dilated proximal urethra related to high-grade obstruction caused by the eroded sling (Lieb and Das, 2003). A review of urethral perforation management is presented in Table 84-15.

Nine urethral perforations (0.6%) were reported in the Australasian data presented by Hammad and colleagues (2005). Thirty percent of these perforations manifested more than 1 year after surgery, and 89% were symptomatic. Presenting symptoms included urinary retention, bleeding, and local pain. One case was discovered incidentally on cystoscopy. Unlike the reported vaginal exposures, 33% of the urethral perforations occurred when the polypropylene sling procedure followed another anti-incontinence procedure. Four (44%) were managed conservatively (two patients were too frail to undergo operative intervention). Five patients (56%) had transvaginal excision. All five who underwent excision were cured and dry.

Management of Midurethral Sling Mesh Perforation of the Urethra. Multiple studies have reported the successful treatment of urethral mesh perforation endoscopically (see Table 84-15). Although we prefer transvaginal surgical excision as a first-line treatment, endoscopic management of small areas of mesh perforation appears to be a reasonable initial option based on a review of the literature. If endoscopic treatment fails, the next step in management of urethral mesh perforation typically involves transvaginal urethrotomy and excision of the perforated mesh. An autologous fascial sling or a Martius labial fat pad graft can be used at the discretion of the surgeon.

For endoscopic management, McLennan successfully managed a MUS urethral perforation endoscopically (2004). Hysteroscopic scissors were used to transect the mesh flush with the urethral mucosa. Catheter drainage was continued postoperatively for 72 hours. The patient remained symptom free and continent at 10 months of follow-up. Wijffels and colleagues (2009) used an endoscopic transurethral approach successfully in three cases of urethral perforation. The visible mesh was grasped with forceps and cut while on traction with scissors. This was performed on both sides of the urethra. One patient had recurrent SUI and had another MUS placed. Baracat and colleagues (2005) successfully used a similar approach for five urethral perforations.

In our opinion, although it is easy to ablate or remove a small portion of perforated mesh endoscopically with the aid of a holmium laser or endoscopic scissors, these patients are likely

to experience recurrence and need further surgeries. Endoscopic excision does not release the tension on the mesh that may be contributing to the perforation and does not provide any interposing tissue. For surgical excision, we will often remove the mesh so that it is no longer in close proximity to the bladder and no longer under tension. The approach and type of incision depend on the location of the perforation.

Other authors have described transvaginal excision of perforated mesh. In 2002, Pit described the management of two cases of urethral perforation. In both these cases the urethra was incised and the mesh was cut at the level of the mucosa. The mesh was then dissected on its medial edge toward the inferior ischiopubic ramus and cut bilaterally, which allowed the mesh to be removed from the periurethral fascia. A Martius graft was placed over the urethra in one case and a cadaveric fascia lata graft was used in the second case. A second MUS was then placed over the tissue bolsters without complication.

Glavind and Sander (2004) reported a urethrovaginal fistula caused by urethral perforation of the polypropylene mesh. Transvaginal mesh excision failed to resolve the fistula, and the patient required two transabdominal fistula repairs until closure was achieved and symptom resolution occurred. Persistent stress incontinence was managed by conservative means with satisfactory results. Sokol and Urban (2008) reported use of the internal urinary sphincter for covering the defect after sling resection. They suggested that this may reduce the risk of fistula formation and be a less morbid option than a Martius flap. Four other additional case reports reported excellent results with use of a midline transvaginal approach with partial mesh excision and closure of the urethra (Haferkamp et al, 2002; Madjar et al, 2002; Lieb and Das, 2003; Wai et al, 2004). The postoperative results reported by each of these investigators were excellent, with all patients achieving symptom resolution after surgical intervention. In two patients, mild recurrent stress incontinence was successfully managed with biofeedback (Glavind and Sander, 2004; Wai et al, 2004). In two patients, continence was achieved with an intraoperative fascial sling, and in a single case, a postoperative fascial sling resulted in satisfactory continence (Vassallo et al, 2003; Wai et al, 2004).

For slings that perforate into the urethra, we prefer an inverted-U incision because this allows for exposure of the proximal urethra, bladder neck, and endopelvic fascia as well as providing a vaginal epithelial flap that avoids overlapping suture lines, theoretically decreasing the risk of a fistula. The distal portion of the inverted U should be distal to the site of the urethral perforation, and the proximal portions of the U incision should extend to the level of the bladder neck in most cases. We will often use a Martius labial fat pad flap to further prevent fistula formation. A PVS is routinely placed if dissection of the sling out of the urethra creates a large defect or a defunctionalized urethra. Mesh excision is typically carried out to the level of the pubic bone or ischiopubic rami. This type of excision leaves behind the arms of the mesh that tunnel into the retropubic space or obturator fossa. It is typically not necessary to enter these spaces because the mesh at this location is no longer under tension and is far from the urethra. We typically leave a Foley catheter for 3 weeks after repair of the urethra.

Midurethral Sling Mesh Perforation of the Bladder

The finding of synthetic mesh within the lumen of the urinary bladder is another particularly distressing complication (Fig. 84-14). This complication is rare after the MUS procedure and, based on a review of the literature (see Table 84-13 on the Expert Consult website), when this complication is reported the incidence falls between 0.5% and 0.6% (Kuuvva and Nilsson, 2002; Ward and Hilton, 2002). The majority of intravesical mesh perforations are most likely the result of an unrecognized cystotomy or placement of the mesh within the urinary bladder at the time of surgery. True migration of the mesh across the seromuscular wall of the bladder into the lumen is much less likely. Thus, performing a complete and thorough cystoscopic examination of the bladder

TABLE 84-15 Management of Mesh Urethral Perforation

*Most common presenting symptoms were urinary tract infection, urethral obstruction, urge urinary incontinence, pain, incontinence, urgency, dysuria, and hematuria.

MUS, midurethral sling; NR, not recorded; PVS, pubovaginal sling.

Figure 84-14. Cystoscopic view of intravesical retropubic sling perforation.

with adequate hydrodistention is critical to minimize this complication. We have found that the trocar may sometimes telescope the bladder wall during insertion and obscure visible bladder perforation. A review of urethral perforation management is presented in Table 84-16.

Patients typically report a variety of symptoms after their MU procedure. A review of seven reported cases in the literature by [Negoro and colleagues \(2005\)](#) found that the typical symptoms are lower abdominal pain, intermittent gross hematuria, recurrent UTI, urgency, frequency, dysuria, and urinary incontinence. Diagnosis is made by cystoscopic examination of the bladder. Imaging modalities such as computed tomography scans and cystography may help in difficult cases but are not a substitute for cystoscopic examination.

Theoretically, transobturator slings should have a lower rate of mesh perforation into the bladder than retropubic slings. However, [Parekh and colleagues \(2006\)](#) reported a case of intravesical mesh perforation after transobturator sling placement and cystocele repair. The patient did not undergo cystoscopy intraoperatively. She initially had mesh on the left side of the bladder, then 6 months later had sling material on the right side of the bladder. She underwent a successful transurethral, transvaginal, and suprapubic mesh resection.

Management of Midurethral Sling Mesh Perforation of the Bladder. Observational treatment is not recommended for mesh perforation of the bladder because the mesh often becomes encrusted, leading to stone formation, persistent lower urinary tract storage and voiding symptoms, recurrent UTI, and intermittent gross hematuria. Different techniques and surgical approaches have been advocated with varying levels of invasiveness, complexity, and success.

For small areas of mesh perforation, the literature supports endoscopic excision with scissors or ablation with the holmium laser as an appropriate initial step. [Oh and Ryu \(2009\)](#) evaluated the efficacy of transurethral resection in 14 patients with intravesical mesh. The intravesical mesh was resected deep into the perivesical fat. The patients had dysuria, hematuria, pelvic pain, and urgency. Six patients had stone encasing the mesh at the time of transurethral excision. With a mean follow-up of 18 months, 13 (92.9%) patients had their mesh completely removed endoscopically with no recurrence. One patient had recurrent bladder stones. One patient had mild SUI and UII, which were controlled with anticholinergics. No further treatment for SUI was performed.

In a case report, [Jorion \(2002\)](#) excised the mesh endoscopically using an offset nephroscope transurethrally and a 5-mm laparoscopic trocar placed suprapubically. Laparoscopic grasping forceps were used to grasp the mesh, and endoscopic shears excised the mesh flush with the bladder mucosa, allowing the mesh to be easily removed. Cystoscopy at 1 month revealed healed mucosa, and the patient was continent and symptom free. In another report by [Tsivian and coworkers \(2004\)](#), the mesh was initially cut endoscopically, but because of an adherent calculus, the mesh could not be extracted endoscopically. Therefore a suprapubic approach was required to remove the stone and intravesical mesh.

Holmium:yttrium-aluminum-garnet (Ho:YAG) laser excision (or vaporization) of encrusted intravesical MUS has been successful in numerous cases ([Hodroff et al, 2004](#); [Barakat et al, 2005](#); [Giri et al, 2005](#); [Lane et al, 2005](#); [Huwyler et al, 2008](#); [Shrotri et al, 2010](#)). Patients often have bladder stones that have formed on the intravesical portions of the sling. For this problem, [Irer and colleagues \(2005\)](#) and [Mahmoud and Wadie \(2007\)](#) described successful endoscopic laser lithotripsy of the calculi and transurethral resection of the sling material. We reserve endoscopic (holmium laser) management of intravesical mesh perforation for very small areas of perforation in select patients.

After endoscopic excision fails or as an initial treatment, mesh perforated into the bladder can be removed from a transvaginal or retropubic approach. For slings that perforate into the bladder at or below the trigone, we prefer an inverted-U incision similar to the aforementioned management of urethral perforation because this allows for exposure of the proximal urethra, bladder neck, and endopelvic fascia as well as providing a vaginal epithelial flap that avoids overlapping suture lines, theoretically decreasing the risk of a fistula. Similar to the management of urethral perforations, we do not excise the entire sling as long as it is no longer under tension and is far from the bladder.

For slings that perforate the bladder dome or other areas of the bladder not accessible from a transvaginal approach, we remove the mesh transabdominally. The sling can usually easily be seen entering the bladder in the retropubic space. Although not always necessary, opening the bladder in the midline usually aids with closure and identification of the exact area of bladder perforation. In general, reconstruction should involve nonoverlapping suture lines and interposition of tissue such as a labial fat pad, greater omentum, or autologous fascial sling.

In a report by [Negoro and colleagues \(2005\)](#), a retropubic approach was used to resect the intravesical portion of the mesh. The bladder was closed with absorbable suture, and catheter drainage was maintained postoperatively. The patient was symptom free and continent at 10-month follow-up. [Volkmer and colleagues \(2003\)](#), [Sweat and colleagues \(2002\)](#), and [Huang and colleagues \(2005\)](#) used a combined transvaginal and abdominal approach to remove the sling in its entirety. One patient had residual urgency and frequency treated with anticholinergics; the other patients had resolution of symptoms but recurrent stress incontinence managed with collagen in one and pelvic floor muscle training and estrogen in the remaining two.

There are several reported cases of successful laparoscopic removal of intravesical mesh after retropubic sling placement. One of these cases used a three-port intraperitoneal approach ([Siow et al, 2005](#)), and the other two used a three-port extraperitoneal approach ([Rehman et al, 2008](#)). All the patients were symptom free and dry after the mesh removal.

Infection and Pain after Midurethral Sling Surgery

Groin and suprapubic pain are potential problems after MUS placement. Thigh and groin pain appear to be more commonly associated with the transobturator approach. A randomized controlled study from Finland ([Laurikainen et al, 2007](#)) revealed that 16% of women in the transobturator (in-to-out) group had groin pain compared with only 1.5% of those in the retropubic MUS arm. In addition, it appears that groin pain persists longer after the transobturator MUSs ([Daneshgari et al, 2008](#)). [Long and colleagues](#)

NR, not recorded.

KEY POINTS: MIDURETHRAL SLING MESH PERFORATION OF THE URETHRA AND BLADDER

- Overall, the incidence of urethral and bladder mesh sling perforation is extremely low in the reported MUS literature.
- As the number of synthetic MUS surgeries continues to increase, physicians need to be mindful of the potential complications, have a high index of suspicion, and be aware of the management options available to treat the patient.
- Conservative observational treatment is not an option for urethral and bladder mesh perforation.
- Currently, for urethral and bladder perforations, transvaginal (or transabdominal) excision of the mesh with closure of the urethrotomy or bladder is our preferred first-line method of treatment in most cases.
- If the repair is tenuous, a vascularized Martius labial fat pad graft can bolster the repair. Furthermore, an autologous fascial sling can be placed at the time of surgery to augment the repair or in a delayed fashion to treat recurrent SUI.

(2009) and Wang and colleagues (2009) also both found the transobturator group to have significantly more postoperative groin and thigh pain. Doo and colleagues (2006) noted persistent suprapubic pain in three (2.2%) women at 5-year follow-up after a retropubic MUS.

De Leval (2003) reported that 15.9% of patients after transobturator MUS surgery had temporary groin pain that resolved after the second postoperative day. Similarly, Krauth and colleagues (2005) reported 14 cases (2.3%) of patients with postoperative perineal groin pain after transobturator MUS surgery. They also noted it to be transient and responding to nonsteroidal anti-inflammatories in all but one case. They hypothesized that the cause of the pain was either subclinical hematoma or a transient neuropathic phenomenon. In 2011, a randomized controlled trial by Teo and colleagues comparing the retropubic and transobturator MUSs was aborted because of a 26.4% incidence of leg pain in the transobturator sling group (1.7% in retropubic MUS group).

Fortunately, chronic groin and leg pain is an uncommon complication after MUS surgery. Roth (2007) found that in three women with persistent groin pain 3 months postoperatively, steroids and local anesthetic were effective for pain relief and had no side effects. Wolter and colleagues published a case report on recalcitrant medial thigh pain after transobturator MUS placement, which ultimately required medial thigh and transobturator exploration by orthopedic surgery and sling excision (Wolter et al, 2008).

Wound-related complications include **minor superficial cutaneous infections and pelvic abscesses**. In their randomized controlled trial from 2002, Ward and Hilton found a 2% rate of vaginal wound infection after retropubic MUS surgery. In 2010, Richter and colleagues found a 0.7% rate of vaginal wound infection in both the retropubic and transobturator MUS arms. In 2004, a case of necrotizing fasciitis was reported in an obese, diabetic patient (Connolly, 2004). This resolved after intensive resuscitation. It is interesting to note that a review of necrotizing fasciitis in gynecologic surgery found that obesity (88%), hypertension (65%), and diabetes (47%) were all factors associated with the development of fasciitis after surgery (Gallup et al, 2002).

Fortunately, severe infection is a rare complication after MUS surgery, and the diagnosis of this complication is variable and can take as long as several years (Choi et al, 2011; Yenilmez et al, 2013). In 2006, Mahajan and colleague reported one case of failed sling and vaginal exposure that was associated with severe groin pain, fever, and chills 10 days postoperatively. The sling was easily removed through a vaginal incision, and mesh cultures were positive for *Bacteroides fragilis*. Complete symptom resolution occurred within 1 week of mesh removal. Abscesses and adductor myositis

have also been reported, manifesting as leg pain, difficulty ambulating, and cellulitis (Goldman, 2006; DeSouza et al, 2007; Karsenty et al, 2007; Leanza et al, 2008; Zumbé et al, 2008). In 2004, Gamé and colleagues (2004) reported an infected obturator hematoma after placement of an ObTape sling that required exploration and drainage. ObTape is no longer available for implantation. In general, severe infectious complications appear to be more common with the older, non-loosely woven polypropylene slings (Babalola et al, 2005).

Management of Midurethral Sling Severe Infection or Pain. In most cases, postoperative groin or leg pain after MUS surgery can be managed with nonsteroidal anti-inflammatory medications, rest, and even physical therapy. Duckett and Jain (2005) reviewed different strategies for managing groin pain after a retropubic MUS placement or similar midurethral sling procedures in 5 (1%) women. Initial conservative management was successful in most patients. Four patients with persistent or severe pain were given a combination of steroid and local anesthetic injections. Two women developed recurrent pain and had the sling excised, with significant pain relief. Medial thigh pain is a common problem after transobturator MUS surgery and, as with retropubic MUSs, can usually be managed conservatively. A prospective study of 100 women who underwent transobturator MUS surgery showed a high 24.4% incidence of groin pain (Lim et al, 2006). Of importance, with conservative treatment the incidence of persistent groin pain 12 months after surgery was only 3.7%.

In instances of chronic mesh pain and severe infection when nonoperative therapy has failed, it may be necessary to attempt a complete mesh excision from both sides of the bone. In the case of retropubic mesh this involves an abdominal and vaginal incision, and in the case of transobturator mesh this involves a medial thigh and vaginal incision. For the complete excision of transobturator mesh we typically consult an orthopedic surgeon to aid with lateral dissection of the sling. In 2012, Reynolds and colleagues published their results of a series of eight patients with chronic groin pain after transobturator MUSs that necessitated mesh excision from the obturator foramen. Five of the eight patients were cured of their pain after a median 8 months of follow-up.

Voiding Dysfunction after Midurethral Sling Surgery

Voiding dysfunction is a common problem after MUS surgery. These voiding symptoms are typically the result of obstruction from the sling as a consequence of the sling being placed too tightly or in the wrong location (too proximally) or associated with pelvic organ prolapse (unrecognized preoperatively or de novo); however, some patients may have voiding dysfunction without evidence of obstruction. Based on anecdotal experience removing hundreds of chronically obstructing slings, we have found that obstructive slings are most likely to be found close to the bladder neck. In addition, we have found that progression of anterior and apical prolapse can cause a nonobstructive sling to become obstructive 10 years or more after placement of the sling. If the diagnosis of sling obstruction is in doubt, urodynamics can be performed to provide confirmation (Volkmer et al, 2003; Levin et al, 2004). Again, whereas most voiding dysfunction after MUS surgery is the result of sling obstruction, not all patients will have obstruction on urodynamic evaluation. Table 84-17 displays a literature review of the management of voiding dysfunction after MUS surgery.

Tables 84-9, 84-10, and 84-11 contain information about rates of voiding dysfunction with MUSs. In general, the rates of de novo urgency and perioperative urinary retention are similar among the different types of MUSs. The most common symptoms of obstruction are an inability to void (urinary retention), incomplete emptying, and de novo urgency and frequency. Over several weeks to a month, the irritative voiding symptoms (urgency, frequency, and pain) become more prevalent as the bladder attempts to adjust to the obstruction.

The optimal evaluation for patients with postoperative voiding dysfunction is poorly defined in the literature. The decision to

CIC, clean intermittent catheterization; NR, not recorded.

perform urethrolisis is usually based on a clear temporal relationship between onset of symptoms and the surgical procedure. Urodynamic studies can be useful in selected cases at the physician's discretion. However, it appears that the temporal relationship correlating symptoms with an antecedent surgical procedure should be the primary criterion in selecting patients for urethrolisis and sling release procedures. Cystoscopy is useful to rule out bladder pathology, urethral mesh perforation, and a hypersuspended bladder neck.

In older nonrandomized studies there did not appear to be a significant difference in postoperative voiding dysfunction between retropubic and transobturator MUS surgeries (Mansoor et al, 2003; de Tayrac et al, 2004). However, in a more recent randomized controlled trial by Richter and colleagues (2010), there was a significantly higher rate of voiding dysfunction necessitating surgery (or permanent catheter) after a retropubic MUS compared with a transobturator sling procedure (2.7% vs. 0%). In addition, the rate of urinary retention (catheter for longer than 6 weeks) was also higher in the retropubic MUS group (3.7% vs. 0.7%).

When selecting patients for the retropubic MUS procedure, it might be helpful to identify preoperative factors predictive of voiding dysfunction and urinary retention after surgery. In a study by Hong and colleagues (2003), 375 patients were analyzed to see which factors predicted urinary retention after the retropubic MUS procedure. Urinary retention, defined as the need to catheterize for 72 hours or longer after surgery, was identified in 32 patients. Twenty-eight patients resumed normal voiding within 3 months, and 4 patients required a transvaginal sling release procedure. On multivariate analysis, only peak flow rate predicted urinary retention. In 2004, a small study of 14 patients showed that low PdetQ-max on a preoperative pressure-flow study correlated with elevated PVR urine in 3 patients who had undergone retropubic MUS surgery (Kawashima et al, 2004).

Tsivian and colleagues (2009) assessed the effect of concomitant vaginal surgery on the outcomes of transobturator sling placement. The group without concurrent vaginal surgery had no voiding dysfunction postoperatively, whereas seven (11%) in the group of patients who had undergone additional pelvic surgery experienced voiding dysfunction. However, Sokol and colleagues (2005), who

looked at factors related to delayed normal voiding in patients with and without concurrent prolapse repair at the time of their retropubic MUS surgery, did not find this same trend. The median days to voiding (8 days vs. 5 days) and rate of urinary retention were similar between patients with and without prolapse repair. However, increasing age, decreasing BMI, and postoperative UTI were independent predictors of increased time to adequate voiding. Previous history of incontinence surgery was the only independent variable predictive of urinary retention. In summary, there does not appear to be a consensus in the literature regarding preoperative factors that contribute to voiding dysfunction after MUS surgery.

Management of Voiding Dysfunction after Midurethral Sling Surgery. Urinary obstruction after MUS surgery is usually transient and can be managed with short-term intermittent catheterization, although occasionally symptoms mandate sling release. Long-term retention after retropubic MUS surgery is a rare complication. In these cases, removal or incision of the sling usually improves the patient's symptoms.

In most cases, postoperative voiding dysfunction can be successfully treated conservatively. In the literature, temporary catheter drainage, CIC, timed voiding, biofeedback, pelvic floor muscle training, and selective medical therapy have all been successful to some degree in managing postoperative voiding dysfunction. In the Kuuva and Nilsson analysis of the Finnish database (2002), 20 of 34 patients with urinary retention resumed a normal voiding pattern after only 1 day to 2 weeks of conservative management. However, 2 patients took a longer 5 and 6 weeks to return to normal voiding. Only 1 of the 34 patients required midline sling lysis, and normal voiding resumed. Also, in that study there were 111 patients with voiding dysfunction but no retention. Thirteen of these patients had voiding dysfunction that lasted up to 4 months, and 2 patients required surgical transection of the sling to achieve a normal voiding pattern (Kuuva and Nilsson, 2002, 2003).

Several reports have shown some benefit of urethral dilation or loosening the sling under anesthesia (Hong et al, 2003; Ozel et al, 2004; Mishra et al, 2005). Mishra and colleagues (2005) performed urethral dilation on 3 of 52 women who had retention 3 months after MUS surgery. Two of the 3 patients voided effectively after urethral dilation. In this series, the postoperative retention rate was significantly higher (23%) than in other published data. It is

our opinion that urethral dilation is of limited usefulness and, if used too aggressively, may be detrimental. There are concerns about the potentially traumatic nature of dilation, which could induce scarring of the urethra or lead to mesh perforation.

Cutting the MUS in the midline through a single vertical vaginal incision is the preferred method to manage persistent voiding dysfunction that results from an obstructive sling within the first 3 months after surgery. In our opinion, after 3 months the sling is fixed along its entire course, and midline sling incision may not achieve enough sling relaxation to resolve voiding dysfunction. In these cases, we perform a more formal sling excision and urethrolisis similar to that described earlier for sling excision after perforation.

Reassuringly, studies by Laurikainen and Killholma (2006), Gamé and colleagues (2006), Clifton and colleagues (2014), and Klutke and colleagues (2001) found that 50%, 70%, 79%, and 94% of patients, respectively, remained continent after sling lysis. In the large review by Klutke and colleagues (2001), 17 of 600 patients (2.8%) required reoperation secondary to urinary retention and persistent obstructive symptoms after retropubic MUS surgery. In their series, sling release was performed at mean of 64 days after MUS surgery. The sling was identified and either released with downward traction for 1 cm or cut in the midline. There was one urethral injury, which was repaired without sequelae. Symptoms resolved in all patients after sling release, all patients voided to completion, and 16 patients remained continent. In 2006, Laurikainen and Killholma performed a nationwide retrospective review of 9040 patients who had undergone MUS surgery. In that study, approximately 50% of the 48 patients who required sling lysis were cured of their voiding dysfunction and remained continent. However, 4 (8.3%) continued to have retention after lysis. There was no difference in continence rate among patients based on interval between MUS placement and sling lysis. Repeat sling lysis or urethrolisis was used to treat refractory retention. Lastly, Gamé and colleagues (2006) presented results of 30 women who required sling lysis with a lateral sling incision over a 4-year period. Of importance, 70% were continent after intervention.

Zubke and colleagues (2004) managed three patients with urethral obstruction after MUS surgery by using a novel surgical technique. They cut the sling in the midline with a transvaginal approach and sutured the edges of the sling to a polypropylene mesh, thus lengthening the sling. All three patients were continent and resumed normal voiding after intervention.

The exact timing of sling incision in the literature is variable; however, most authors recommend waiting at least 2 weeks (Long et al, 2004; Glavind and Glavind, 2007) before sling incision in cases of sling obstruction. Even though Kuuva and Nilsson (2002) reported return to normal voiding after 6 weeks of conservative management, the majority of studies do not support waiting more than 4 weeks. In our opinion, in cases of significant obstruction or retention, the sling should be incised within 4 weeks of surgery. Also, in our experience, even though some patients may return to “normal voiding” with conservative management, they often have persistent urgency and frequency.

Sexual Dysfunction after Midurethral Sling Surgery

Varying degrees of sexual impairment have been reported after MUS surgery. The rate of sexual impairment after MUS sling surgery is as high as 20% (Mazouni et al, 2004). In the study by Mazouni and colleagues (2004), 71 women were prospectively followed after they underwent retropubic MUS surgery. In that study, 55 women had no sexual impairment before surgery, and 14.5% of the women developed dyspareunia and 5.4% experienced decreased libido after surgery. However, in a more recent study of 1112 women by Stav and colleagues (2010b) not designed to specifically look at sexual dysfunction, the rate of de novo dyspareunia after MUS surgery was only 3%.

Marszalek and colleagues (2007) performed a cross-sectional analysis and noted that a 14.3% deterioration in sexual function was significantly associated with de novo urgency, dyspareunia, and

KEY POINTS: MIDURETHRAL SLING VOIDING DYSFUNCTION

- Based on the available data, it appears that long-term urinary retention and obstructive voiding dysfunction are rare after the MUS procedure.
- Although definitions of urinary retention and indications for management vary in the reported literature, most patients are initially managed conservatively.
- Anecdotal cases have shown modest benefit from urethral dilation.
- For patients with persistently elevated residual urine and bothersome symptoms refractory to conservative management, transvaginal sling release procedures consistently provide resolution of symptoms with maintenance of continence in the majority of patients. We recommend a waiting period of at least 2 to 4 weeks before sling release.
- Sling release should be attempted through a small midline vaginal incision using minimal dissection.

the sensation of incomplete emptying. In 2008, Demirkesen and colleagues compared sexual satisfaction after MUS surgery and Burch colposuspension. In that study, 54% expressed a negative change, with most reporting dyspareunia. The MUS appeared to more adversely affect sexual satisfaction, but the difference was not significant. Kuhn and colleagues (2009a) reviewed the impact of sling removal on postoperative female de novo dyspareunia and found that the pain improved significantly.

There is also evidence that treatment of urinary incontinence can improve sexual function after surgery. In the randomized controlled trial by Ward and Hilton (2008), the rate of dyspareunia actually decreased from 34% preoperatively to 13% 5 years after sling surgery. In 2009, Bekker and colleagues published the results of a retrospective evaluation of sexual function in 136 women after MUS surgery. The authors found that 21.3% of women reported improved sexual intercourse after surgery and 5.9% reported worsened sexual intercourse. The authors mostly attributed the improved sexual function to a significant decrease in coital incontinence.

Other Complications after Midurethral Sling Surgery

A diverse group of complications have been reported with the MUS, in addition to those mentioned previously. These include infection, bleeding, vascular injury, bowel perforation, and death. UTI is probably the most common and easily treatable complication of MUS surgery. Rates of UTI after MUS surgery range from 22% to 31% in large randomized controlled trials (Ward and Hilton, 2002; Richter et al, 2010).

Another less common complication is intraoperative and postoperative bleeding. This complication is usually variably and subjectively reported in the literature. A review of the literature reveals that severe bleeding or hematoma occurs in approximately 2% to 3% of patients and can usually be managed with observation or local compression (see Table 84-13 on the Expert Consult website). Table 84-13 also shows that in 8 of 10 studies reviewed comparing different MUS surgeries, bleeding complications occurred more commonly after retropubic MUS surgery. In their study, Wei and colleagues (2012) found the average estimated blood loss after MUS surgery to be 156 mL. In 2004, Flock and colleagues (2004) reported that 4.1% of 249 patients experienced a hemorrhage of 300 mL or more and required surgical intervention after retropubic MUS surgery. Tseng and colleagues (2005) performed ultrasonography on all 62 women after MUS surgery and found that 8 (12.9%) patients had significant retropubic hematomas greater than 5 cm on the day after surgery. Only 1 patient required hematoma evacuation, and in the rest, repeat ultrasonographic examinations 1 month after surgery revealed the

hematomas had resolved. Of interest, this study revealed that a postoperative hematoma may be a relatively common asymptomatic event after trocar passage.

Serious complications such as vascular perforation, intestinal perforation, or even death remain extremely rare. The rate of serious vascular complications in the Finnish registry was 0.07% (Kuuva and Nilsson, 2002). Comparably, the Austrian registry reported a bowel perforation rate of 0.04% (Tamussino et al, 2001). In 2007, Deng and colleagues (2007) reviewed the complications reported to the FDA MAUDE database. The authors found that of 928 reported complications, 161 were considered major. The major complications included 39 vascular injuries, 38 bowel injuries, and 10 deaths.

REGULATORY AND LEGAL ISSUES RELATED TO SLING MESH COMPLICATIONS

The FDA approved the first MUS for use through the 510(k) approval process in 1998. It is interesting to note that all subsequent MUSs have also been approved for use through this process (Secunda, 2011). The 510(k) approval process for Class II products (mesh products fall into this class) allows medical device manufacturers to bypass the normal premarket approval procedure as long as the new device is substantially equivalent to an existing product (U.S. Food and Drug Administration, 2013a, 2013b). Once the FDA determines that a product is substantially equivalent to an existing product, the company receives a letter of approval to market the new device.

The success of MUSs for incontinence led to the development of mesh products for pelvic organ prolapse repair. Subsequently, the FDA determined that these products were substantially equivalent to existing mesh products already approved, and in turn FDA's 510(k) approval process led to the rapid approval of these products also. The FDA and many physicians believe that the 510(k) approval process is a necessary and important practice that allows for medical device advances to occur more rapidly. Of note, through the Freedom of Information Act (5 U.S.C. § 552(a)(2) (Title 5 United States Code section 552 subsection a2)), all FDA letter communications to manufacturers are available online.

However, while the use of mesh during pelvic organ prolapse repairs has increased, so too have complications related to its use. In October 2008, the FDA released a public health notification (PHN) alerting the public about "rare" complications and problems related to transvaginal mesh products used for pelvic organ prolapse. In 2011, the FDA modified this alert by removing the term "rare" and stating that surgical mesh for pelvic organ prolapse repair does not conclusively improve outcomes over traditional nonmesh or native tissue repairs and is associated with unique potentially serious adverse outcomes (U.S. Food and Drug Administration, 2011).

If a product approved by the FDA through the 510(k) process is found to have potential serious adverse health consequences, the FDA can require the manufacturer to perform costly 522 postmarket surveillance studies. In the case of mesh for pelvic surgery, the FDA was alerted to potential serious adverse events through the MAUDE database and reports in the urologic and gynecologic literature. In January 2012, the FDA mandated that all manufacturers of synthetic prosthetic mesh and biologic graft materials marketed for pelvic organ prolapse repair and single-incision sling products perform 522 postmarket surveillance studies. MUS products (except single-incision slings) were excluded from this mandate because in September 2011 an FDA advisory panel deemed existing MUS products "safe and effective" and recommended that these products not undergo 522 postmarket surveillance. For future MUS products, the FDA determined that the 510(k) approval process is still applicable as long as well-designed bench or animal studies are included with the 510(k) application. However, premarket clinical studies for new SUI products may be required if the FDA determines that there is a need for clinical information to demonstrate substantial equivalence to an existing product (Baxley, 2011).

Even though the FDA has determined that existing MUS products are safe and effective, this unfortunately does not prevent MUSs from being caught up in the fervor of litigation related to products used for pelvic organ prolapse repair. In June 2010, a settlement was reached to halt the first class-action lawsuit against the manufacturer of ObTape (Mentor-Porgés) (Chapple et al, 2013). To date, AMS (parent company Endo Pharmaceuticals), Ethicon (Gynecare, parent company Johnson & Johnson), Boston Scientific, and C.R. Bard have all been targeted by multidistrict federal litigation for complications related to their MUS products. C.R. Bard and Ethicon have already discontinued their mesh products, and as litigation increases, other manufacturers may decide to follow suit. Currently, most litigation is directed at device manufacturers; however, this could change. It is important for pelvic surgeons to continue to thoroughly counsel their patients about the permanent nature of mesh products and the potentially serious complications related to their use.

Pelvic Reconstructive Surgery

Complications of Mesh in Pelvic Reconstructive Surgery

Evaluation of Mesh Complications

Treatment of Mesh Complications

Conclusion

Urologists most often use mesh for the surgical treatment of urinary incontinence and pelvic organ prolapse. This topic becomes increasingly important to surgical training as the number of patients undergoing such procedures rises annually secondary to the increasing number of women at risk and the refinement of surgical technique into more minimally invasive outpatient approaches (Jones et al, 2010; Bradley et al, 2011). Augmentation of traditional native tissue repairs with nonabsorbable synthetic mesh products demonstrated great promise in short-term outcome studies; however, longer term evaluation revealed a 19% erosion rate and a 28% incidence of dyspareunia (Committee on Gynecologic Practice, 2011). Urologists worldwide must now balance the higher anatomic success rates of mesh repair against the longer term risks of erosion and other complications, some of which cannot be completely reversed.

The trend toward dominance of mesh-augmented over native tissue repairs for the treatment of incontinence and prolapse was most pronounced from 2000 to 2006, after which overall mesh use declined for prolapse and incontinence procedures (Wu et al, 2009; Rogo-Gupta, 2013). The exact reasons for the shift are unknown; however, many authors suspect multifactorial influences. Professional organizations began questioning the benefits of mesh over nonmesh options in 2004; in 2008, the U.S. Food and Drug Administration (FDA) released its first in a series of public communications regarding the safety of mesh in pelvic surgery (Sung et al, 2008; Maher et al, 2011; Walter et al, 2011).

Although individual synthetic products in pelvic surgery have been placed under particular scrutiny, concerns have been raised regarding multiple aspects of these procedures, including material type and location and method of placement. The Society of Gynecologic Surgery questioned the appropriateness of mesh for posterior compartment prolapse, a concern that was echoed by the Cochrane Collaboration (Sung et al, 2008; Maher et al, 2011). Others publicly questioned method of placement. In 2011, the Society of Obstetricians and Gynaecologists of Canada stated that trocar-guided placement devices should be considered novel techniques and were associated with adverse sequelae (Walter et al, 2011). A summary of available data on mesh-related complications was devised in a collaborative effort between the American College of Obstetricians and Gynecologists and the American Urogynecologic Society in 2011 (Committee on Gynecologic Practice, 2011). The Committee on Gynecologic Practice recommended counseling patients regarding the risk of mesh exposure (range 1% to 19%); buttock, groin, or pelvic pain (range 0% to 18%); de novo dyspareunia (range 2% to 28%); and reoperation (range 1% to 22%).

The increasing incidence of mesh complications in urologic surgery suggests that a re-evaluation of their use in practice is warranted. Complications range from mild and self-limited to chronic and irreversible (Committee on Gynecologic Practice, 2011). For example, anatomic obstruction of the urinary tract may resolve with removal of the implant; however, chronic pain may persist for years. Although there is no international consensus regarding standard practice of mesh in incontinence and prolapse surgery, guidelines exist for surgical planning, patient counseling, and obtaining appropriate informed consent (Committee on Gynecologic Practice, 2011).

Prolapse and incontinence surgery is generally considered safe and minimally invasive, and all patients, whether they undergo mesh or nonmesh surgery, are at risk for complications, including infections, urinary urgency and urge incontinence, pelvic organ prolapse, and outlet obstruction. In this chapter, we discuss etiology, evaluation, and treatment of mesh complications in pelvic reconstructive surgery. Our primary focus is female patients with pelvic organ prolapse and urinary incontinence; however, comparable complications may be seen in men undergoing pelvic surgery (Bauer et al, 2010; Weinberger et al, 2013).

KEY POINTS: INTRODUCTION

- Higher anatomic success rate of mesh repair must be balanced against complication risk.
- Complications include exposure (1% to 19%); buttock, groin, or pelvic pain (0% to 18%); de novo dyspareunia (2% to 28%); and reoperation (1% to 22%).

PELVIC RECONSTRUCTIVE SURGERY

Epidemiology

The number of women in the United States with pelvic floor disorders is projected to increase rapidly in the coming decades from 28 to 44 million between 2010 and 2050 (Wu et al, 2009). Historically, at least 11% of these women undergo at least one surgical procedure during treatment (Maher et al, 2011); this is likely to translate to a potentially overwhelming number of patients seeking care in an already overburdened health care system. These increased demands on the health care system in the wake of health care reform may

place added pressure on urologic surgeons as the future of health care delivery is unclear. Urologic surgeons must feel confident in their repair techniques and be prepared to offer cost-effective, reliable treatments with acceptable long-term outcomes. Urologic surgeons must feel comfortable in regard to the outcomes of mesh repair techniques and their ability to identify and address mesh-related complications.

Risk factors for incontinence differ by gender. In women who often also experience pelvic organ prolapse, risk factors include age, parity, obesity, menopause, genetic predisposition, and chronic pelvic strain. In general, tissue damage from mechanical trauma and hormone effects combined with genetic predisposition and lifelong behavioral patterns culminate in the pattern of symptoms that brings patients to physician offices. Treatment aims at addressing multiple components of pelvic floor dysfunction.

Urinary incontinence treatment is recommended for symptomatic patients (Dmochowski et al, 2010). Over the past three decades, the most commonly performed surgery for stress urinary incontinence has shifted from needle suspensions to mid-urethral slings, which are recommended by the American Urological Association as the most durable treatment option for stress incontinence. Alternatives that are less commonly performed, but still a part of the urologist's armamentarium, include slings of non-synthetic material, needle suspensions, urethral bulking agents, and artificial urinary sphincters. Prolapse repair is offered to symptomatic patients who have failed conservative management. Symptoms range from vaginal bulge to obstructive urination or defecation to dyspareunia. Experts also recommend treatment for patients with end-organ damage from prolapse such as hydronephrosis, vaginal ulcerations, urinary retention, or cystoscopic findings of urinary obstruction. For the treatment of prolapse of the pelvic organs, the current standard of surgical repair is a mesh suspension of the prolapse to the sacral promontory (sacrocolpopexy). Mesh also can be placed vaginally to repair isolated or multiple compartment prolapse.

Historically, native tissue prolapse repair was reported to have a 30% failure rate; however, more recent reviews highlight much higher subjective success rates (Lee et al, 2012). Mesh was adopted to augment native tissue repair to improve objective outcomes as measured using the Pelvic Organ Prolapse Quantification or Baden-Walker systems. Perfect support is defined as stage 0; however, 75% of asymptomatic women have greater than stage 1 findings. As a result, many patients who were satisfied with their surgical outcomes were categorized as failures if their objective measures did not meet criteria for success. This demonstrates the discrepancy between objective prolapse and subjective symptoms, which is of utmost importance when considering surgical intervention to improve quality of life. Pelvic reconstructive surgeons correct anatomy to restore function and improve quality of life. Surgical outcome should be evaluated not only by anatomic improvement but also by symptomatic improvement and demonstrable impact on overall quality of life. We should strive to minimize complication rates for procedures.

For surgeons, expertise with traditional and mesh-augmented pelvic reconstructive surgery is recommended. Surgeons should counsel patients on the risks and benefits of all options, while providing recommendations and obtaining informed consent. Counseling should include the risk of late-onset complications that are difficult to predict. Factors affecting complications that may present years after placement include vaginal atrophy, low-grade infection, tissue aging, or a dynamic host-graft response not completely understood. The fact that many of these risk factors are nonmodifiable makes prevention of these complications challenging.

Materials

Synthetic mesh is one of many materials used in pelvic reconstructive surgery and was introduced into prolapse repair to improve long-term durability compared with repairs using native tissue, fascia autografts, allografts, or xenografts. Synthetic material has

many advantages, including easy placement, broad coverage, and tension-free placement. Designed to replace damaged support structures, mesh products may be hand-cut and customized to each individual patient or purchased in premade kits. Kits are available for the correction of urethral hypermobility and prolapse of the anterior, apical, and posterior vaginal compartments and range in their mechanisms of placement and fixation (Washington, 2011). Examples of vaginally placed mesh techniques include trocar-guided placement, tine or suture fixation, and implants that are adjustable after implantation. When anterior compartment repair uses trocars, the arms traverse the adductor and obturator muscles bilaterally. In procedures without trocars or single-incision procedures, the implant does not traverse the adductor or obturator muscles; rather, it is fixed to fascia or ligaments themselves. Trocar-guided apical and posterior repair kits pass mesh through the sacrospinous ligaments and exit the skin in the gluteal area. Mesh also can be placed abdominally for prolapse correction to suspend the uterus, cervix, or vaginal cuff to the sacrum. Despite the popularity of mesh kits, the most commonly used mesh product in gynecologic surgery is a free mesh hand-cut by the surgeon.

Mesh graft composition has evolved since its initial introduction into pelvic surgery. The most widely used products are made of polypropylene because this material has demonstrated significantly fewer morbid complications compared with prior material. Polypropylene, categorized as a type I macroporous monofilament mesh, has been implicated in long-term complications only more recently; it remains unclear whether these complications are due to the material itself, host response, surgical factors, or a process not yet identified. Other products have been largely abandoned because of associations with infection, graft rejection, and pain, as was seen with Mersilene mesh (Ethicon, Somerville, NJ) and silicone slings used in the 1960s and 1980s, respectively (Williams and Telinde, 1962; Stanton et al, 1985; Duckett and Constantine, 2000).

The process of mesh degradation and tissue incorporation begins at insertion (Clave et al, 2010). Local inflammation and granular tissue creation converts to dense fibrous tissue over approximately 2 to 3 months, incorporating the graft into the surrounding tissue. Concurrently, mesh shrinkage occurs wherein there is a 30% to 60% decrease in graft size (Garcia-Urena et al, 2007).

The increasing number of mesh products approved and marketed makes thorough evaluation of any single product increasingly challenging. This dilemma is not unique to urologic surgery and has been described in other surgical specialties including orthopedics: A hip replacement device was implanted in more than 100,000 patients before it was recalled in 2010 because of a 49% 6-year revision rate (Curfman and Redberg, 2011). In 2011, the FDA called for nationwide randomized controlled trials to evaluate the use of mesh in pelvic reconstructive surgery after their determination that existing literature was insufficient to form proper conclusions (U.S. Food and Drug Administration, 2011). Similar concerns have been raised in other countries.

Although the future of mesh in pelvic reconstruction is unclear, it will likely continue to be used by experienced surgeons in carefully selected patients in whom the benefits outweigh the risks. Surgeons must be aware of the factors that contribute to mesh complications and obtain proper informed consent before mesh placement for any indication.

KEY POINTS: PELVIC RECONSTRUCTIVE SURGERY

- A discrepancy exists between objective findings and subjective success for prolapse and incontinence repair.
- Complications may be due to synthetic material, host response, surgical factors, or a process not yet identified.
- In 2011, the FDA called for nationwide randomized controlled trials to evaluate the use of mesh in pelvic reconstructive surgery.

COMPLICATIONS OF MESH IN PELVIC RECONSTRUCTIVE SURGERY

Complications related to mesh use have gained international attention more recently. More than two decades after the widespread incorporation of polypropylene mesh into pelvic reconstructive procedures, new data suggest 10% of patients experience serious complications, including some that cannot be completely reversed (Committee on Gynecologic Practice, 2011). Some complications are minimally morbid and can be managed conservatively in outpatient settings (Niro et al, 2010). This includes vaginal mesh exposure, a finding that resulted in the discontinuation of much research that may have revealed the more serious long-term complications had the trials continued. Additional complications include bleeding, infection, fistula, pain, dyspareunia, organ perforation, obstruction, and dysfunction. The details of each are discussed later in this chapter. Although the exact etiology of many complications is unknown, we discuss existing opinion regarding the factors contributing to mesh complications.

Etiology of Complications

Complications of mesh insertion occur secondary to modifiable and nonmodifiable factors. For example, when mesh is placed superficially, patients may experience bleeding, pain, dyspareunia, or infections from local ulceration and necrosis. Surrounding tissue may be predisposed to such reaction in cases of extensive local dissection, previous surgery, radiation, immunosuppression, or other local trauma. Sutures also must be selected and placed with care because wound separation would undoubtedly lead to mesh exposure. Hemostasis is essential when using mesh. Anemia may contribute to poor tissue healing, and hematomas may become infected, place pressure on suture lines, and contribute to wound separation. Large hematomas, which may cause pain, cause urinary obstruction, or require drainage if they do not spontaneously resolve, are seen less often.

Mesh is subject to bacterial contamination that may not be entirely prevented by sterile surgical technique (Culligan et al, 2003). This process is not unique to urologic surgery as demonstrated in examinations of implants used in other types of surgery (Gristina et al, 1985). Strategies to decrease contamination including hair removal, preoperative antiseptic washes, and antibiotics have been hypothesized to decrease implant contamination (Darouiche et al, 2010). Some products have protective sheaths for placement to avoid direct contact with the skin edge because this is likely a source of bacteria even after standard surgical preparation. In microscopic examinations of explanted mesh, bacterial contamination is followed by biofilm formation manifesting clinically as drainage or with nonspecific symptoms such as fatigue, fever, and chills. This process of low-grade infection may continue for a long time or escalate into cellulitis, wound separation, pain, bleeding, discharge, and erosion or organ infection.

The integrity of surrounding tissue affects surgical outcomes. Metabolism initiates foreign body degradation, and neovascularization assists in tissue incorporation. These processes are intrinsic to the patient and not modifiable by the surgeon. Sensitivity of the urethra and vagina to local estrogen effects suggests that postmenopausal women may be more subject to bleeding, infection, or poor wound healing. As a result, some surgeons chose to administer preoperative estrogen, which has been demonstrated to alter vaginal cytology in women with atrophic vaginitis (Vaccaro et al, 2013).

Placement method has an impact on some complications of mesh insertion. Location of fixation and trocar placement largely contribute to pain complications of mesh in urologic surgery and may vary significantly (Hinoul et al, 2007). Retropubic sling arms can incorporate urethra, bladder muscularis, levator musculature, and obturator muscle when a trocar is passed close to the pubic bone, rectus muscle, or lumbar nerve branches in their trajectory. Arms also may densely adhere to the retropubic periosteum. Trans-

obturator slings similarly may adhere to urethra, bladder, and levator before traversing the obturator muscles and adductor musculature responsible for hip flexion and adduction (Fig. 85-1). Nerve damage from trocar passage or implant placement may manifest immediately as sharp, focused pain. Nerve injuries that manifest late are typically subtle. Women may report decreased or lack of sensation to the labia, clitoris, or perineum.

Complications of the perioperative period range in severity. Mild complications such as voiding dysfunction or discomfort often resolve spontaneously with minimal intervention, and careful monitoring of these patients is recommended. When complications persist past the perioperative period or do not resolve with conservative management, they may require medication or intervention. Such complications include prolonged voiding dysfunction, urinary obstruction, vaginal pain or dyspareunia, erosion into an organ or exposure through the vaginal wall, and defecatory dysfunction (Fig. 85-2). Long-term complications may manifest months or years after insertion.

Anatomy of Complications

Complications may be related to neurologic, musculoskeletal, or organ injury. Understanding of the innervation and organs surrounding the area of mesh placement is recommended for all surgeons who place mesh for reconstruction. This knowledge is essential for proper mesh placement and thorough evaluation of complications postoperatively.

Genitourinary Tract and Surrounding Structures

Complications of mesh placed for support of the bladder or urethra range in severity. Lower urinary tract symptoms are the most commonly reported, and pain may occur at any point in bladder filling or emptying. Spasmlike pain, pain with position change, or activity-related pain may indicate involvement of the levator ani, obturator muscles, or fascia. Implanted mesh in the bladder wall is often associated with urgency and urge incontinence, whereas urethral damage may cause dysuria and urethral pain. Mesh can penetrate partially or completely through the bladder wall and can be found penetrating the mucosa, under the mucosa, or in the muscularis. Mucosal involvement is associated with complications of exposure such as hematuria and stone formation, whereas mesh in the muscularis rarely causes such complications (Fig. 85-3). Complete obstruction from mesh placement typically manifests with urgency, frequency, inadequate emptying, or elevated postvoid residuals. Incomplete obstruction has a similar presentation. Vaginal intercourse can be painful when mesh is placed in the vaginal muscularis superficially.

Mesh penetration into the urethra or bladder typically manifests with hematuria, urinary tract infections, or pain. Retropubic sling arms may damage the ilioinguinal nerve (L1) and the genital branches of the genitofemoral nerve causing sharp localized pain, whereas obturator arms may damage the posterior branches of the femorocutaneous, posterior cutaneous (L2-S3), pudendal, perineal, inferior anal, or obturator nerves (L5-S1) (Fisher and Lotze, 2011).

Mesh also may become fixated to the bony pelvis causing osteomyelitis or pain from traction as mesh shrinkage occurs between tensioned arms. Mild periosteal damage or inflammation is self-limited; however, severe localized pain may warrant diagnostic imaging (Grimes et al, 2012). Tenderness to palpation of the pelvis may be seen during this process or when implants adhere to the inferior pubic rami. Retropubic hematomas occur in 25% of sling placements (Giri et al, 2005). Trauma to the anterior rectus muscle following retropubic sling is often positional, is relieved with rest, and resolves with time. Trocar-guided transobturator mesh may be associated with myositis, hip and thigh pain from muscles innervated by the obturator (L2-L4) and sciatic (L4-S3) nerves. Such pain occurs with abduction, adduction, lateral thigh rotation, walking, and prolonged sitting. When these complaints occur immediately postoperatively, they are often associated with intraoperative

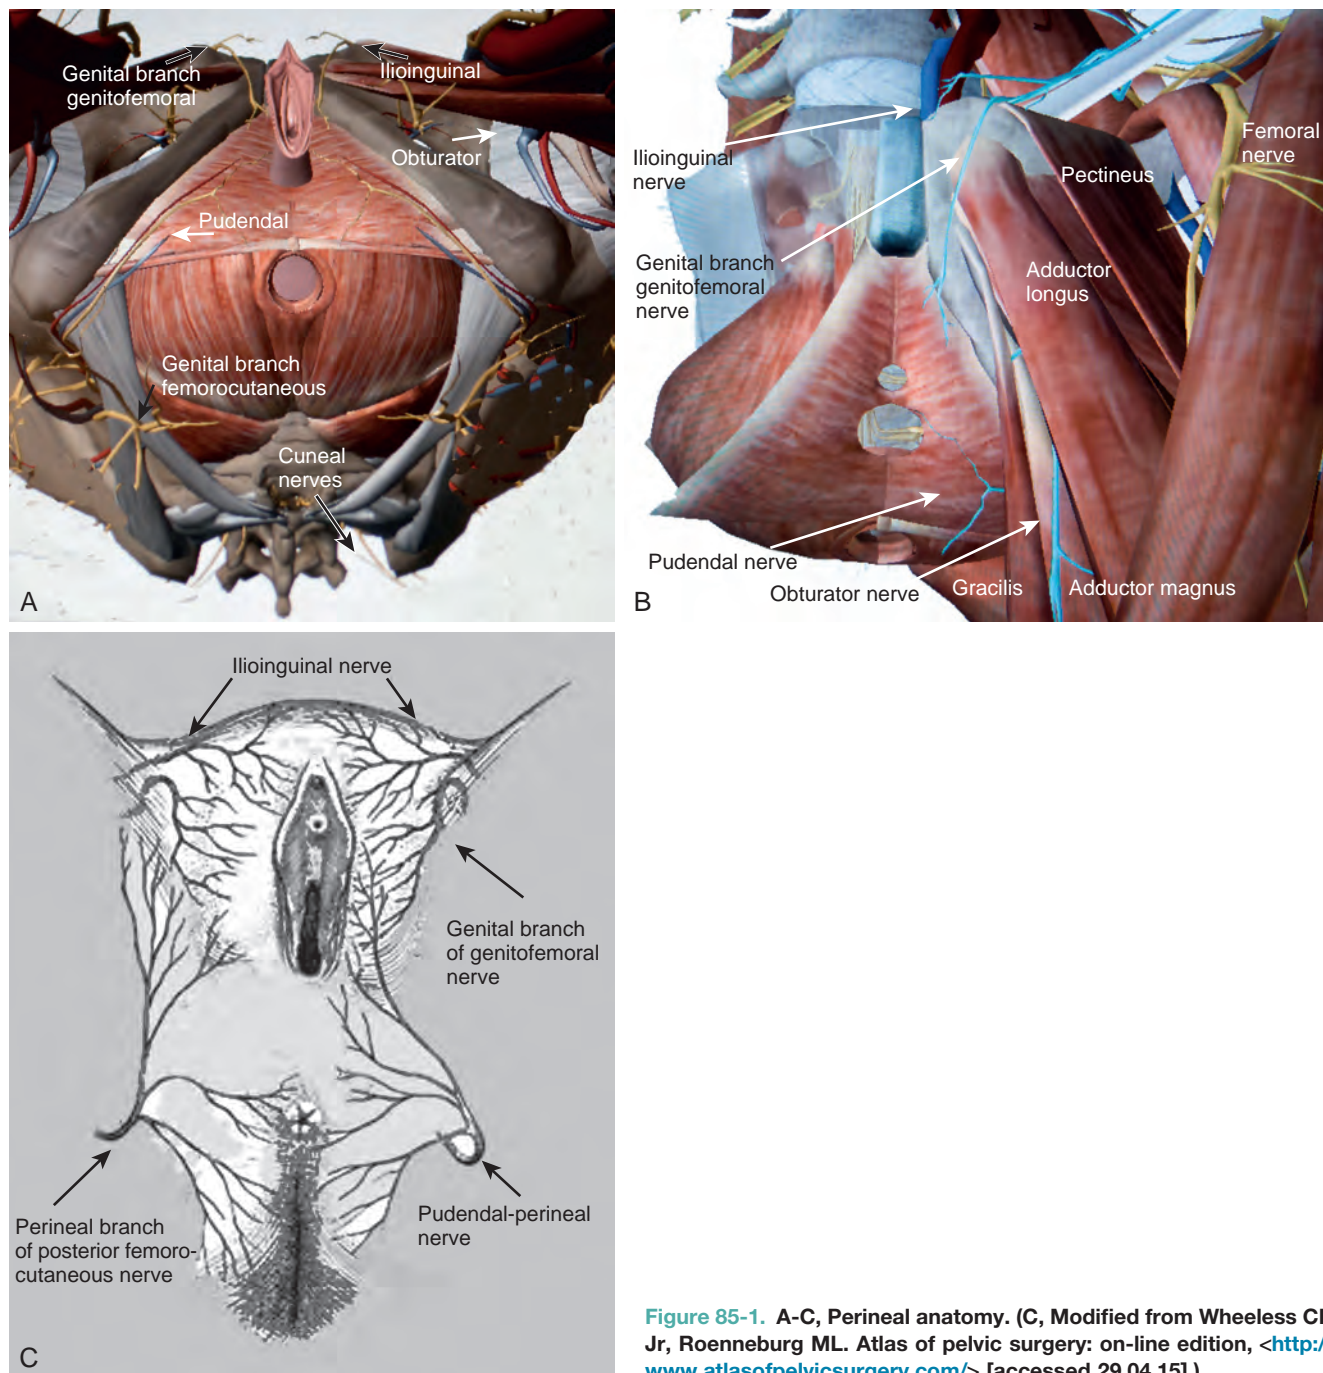

Figure 85-1. A-C, Perineal anatomy. (C, Modified from Wheless CR Jr, Roenneburg ML. *Atlas of pelvic surgery: on-line edition*, <<http://www.atlasofpelvicsurgery.com/>> [accessed 29.04.15].)

positioning; with severe or prolonged pain of this type, the surgeon should consider mesh complication in the differential diagnosis.

Vagina and Pelvic Floor

Musculoskeletal complications of mesh placed vaginally for prolapse are similar to complications described for the bladder and urethra. Mesh placed for apical prolapse correction may additionally affect the coccygeus muscle overlying the sacrospinous ligament or nearby piriformis muscle, innervated by the piriformis nerve (L5-S2). In such cases, patients report pelvic floor spasms, dyspareunia, and prolonged pelvic pain. Pain may radiate from the gluteus, innervated by inferior gluteal nerve (S1), to the vagina. Spasms may cause incontinence or obstruction of urination or defecation, which can be particularly troubling for patients.

Mesh placed for sacral suspension also has been associated with complications including sacral pain, osteomyelitis, and nerve root entrapment and disk damage. Such rare complications occur when the sutures are placed below the sacral promontory at the S1, S2, or S3 foramina. When the uterus or cervix is left in situ, mesh erosion into these organs may manifest as bleeding, cramping, drainage, or pain. Damage to lateral vasculature including obturator, uterine, and vaginal arteries also has been reported. Nerve injury to the lumbosacral plexus may occur during dissection and mesh fixation.

Gastrointestinal Tract and Surrounding Structures

Mesh placed for repair of rectocele may cause muscular pain. Damage to the levator or gluteus maximus can occur with

trocarguided mesh, whereas damage to the anal sphincters may occur from fixation or local dissection. Both techniques have been associated with dyspareunia and defecatory dysfunction. Sharp focal pain results from injury to the sciatic or pudendal nerves and typically manifests immediately after insertion.

KEY POINTS: COMPLICATIONS OF MESH IN PELVIC RECONSTRUCTIVE SURGERY

- Complications occur in 10% of patients, and some cannot be completely reversed.
- Neurologic, musculoskeletal, and organ injury range in severity and time of presentation.

Figure 85-2. Vaginal exposure (arrows).

EVALUATION OF MESH COMPLICATIONS

History

Evaluation of mesh complications begins with a careful, detailed history (Fig. 85-4). In cases of patient referral, operative and progress notes should be reviewed for complications or issues or to corroborate the patient's recollection of events. Concomitant procedures, planned procedures that were aborted, or intraoperative consultations by specialists warrant special attention. Next, a timeline of presenting symptoms should be obtained in relation to time since surgery. Lastly, details of each symptom should be described, including quality, severity, and relieving and exacerbating factors. The absence of significant findings on initial examination does not reliably rule out future complications, and patients should be counseled regarding the possible need for repeat evaluations and long-term complications.

Obstruction of urination or defecation after surgery may manifest as complete or incomplete obstruction. Symptoms include urgency, frequency, and need to strain or change positions while emptying. Patients with urinary obstruction may have high or normal postvoid residuals and the presence or absence of inadequate emptying symptoms because they may have adopted compensatory strategies to achieve bladder emptying. The overall incidence of urinary obstruction requiring intervention in patients after mid-urethral sling procedures is approximately 8% (Dmochowski et al, 2010). Etiologies include penetration of sling material into the bladder or urethra, complete urethral fixation, sling excessively tight, periurethral fibrosis, or secondary bladder prolapse.

In patients who present with pain, noting the severity, timing of onset, and relieving and exacerbating factors provides necessary information in determining the etiology. Routine postoperative pain is self-limited and resolves with medical management and within the perioperative period, although the exact duration is variable. The concurrent processes of tissue healing and mesh shrinkage also may contribute to pain, which is typically described as constant, dull, and worsened with activity or increases in intra-abdominal pressure. Local (i.e., warm water, ice, topical medications) and systemic (i.e., pain control, bladder relaxants, stool softeners)

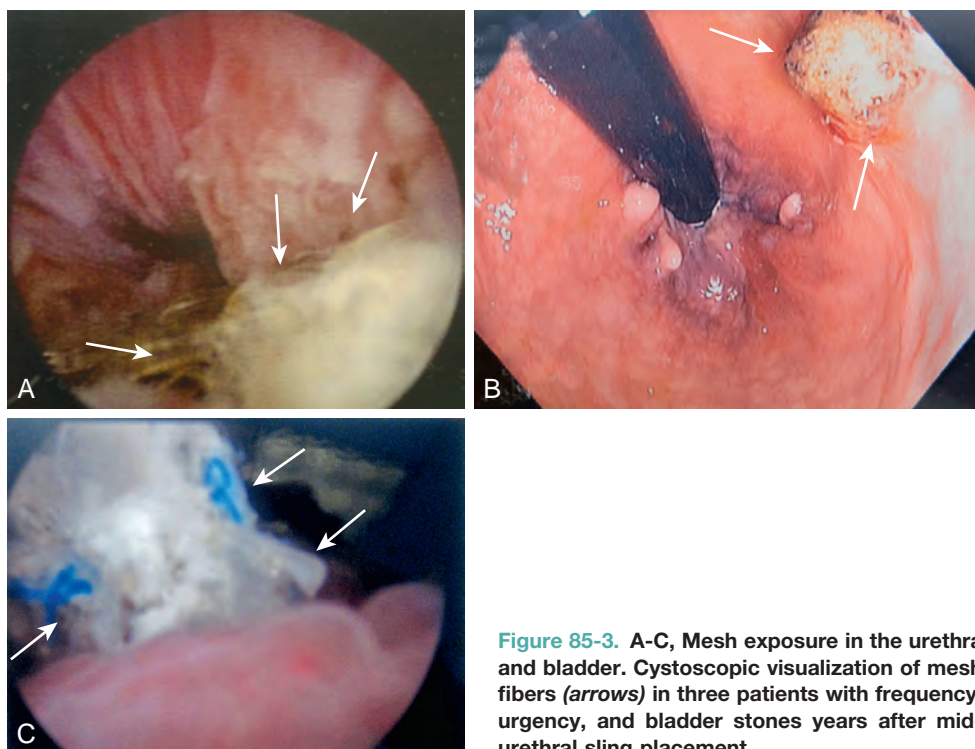

Figure 85-3. A-C, Mesh exposure in the urethra and bladder. Cystoscopic visualization of mesh fibers (arrows) in three patients with frequency, urgency, and bladder stones years after mid-urethral sling placement.

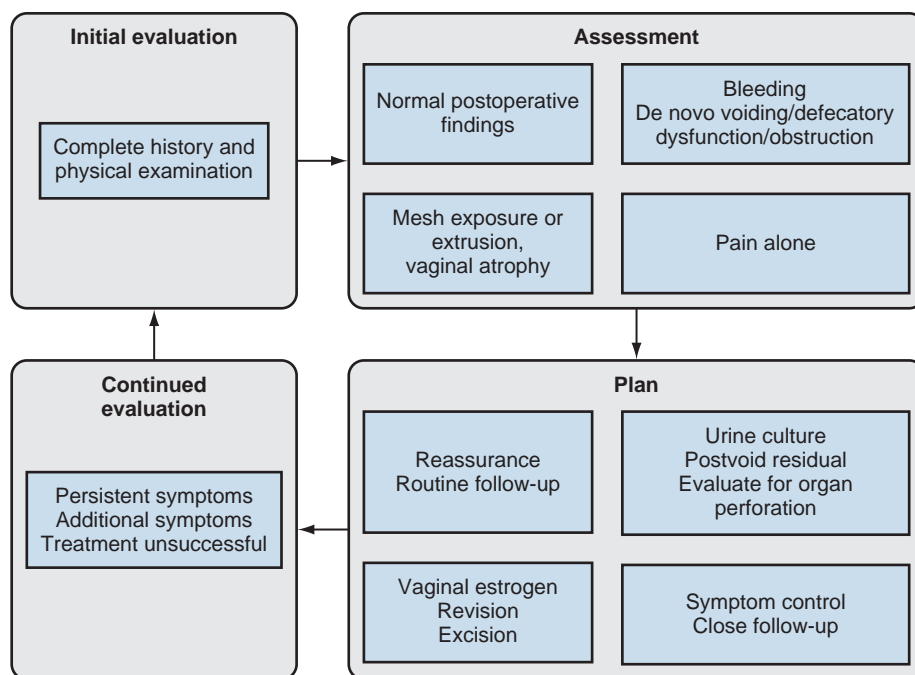

Figure 85-4. Treatment algorithm for patients presenting with possible mesh complications.

treatments may be appropriate. Close follow-up and repeat examinations are recommended to monitor for improvement. A history of prolonged pain and bleeding of the bladder or rectum suggests mesh penetration and should be evaluated further. Fatigue has been reported in patients with chronic infection.

Some patients may report pain out of proportion to examination findings or experience pain despite local and systemic treatments. These patients warrant further evaluation as detailed subsequently because pain in susceptible patients may trigger the development of symptoms similar to those seen in patients with chronic pelvic pain. Obtaining a history of patient experience after prior surgeries; episodes of prolonged or severe pain; or pain syndromes such as interstitial cystitis/painful bladder syndrome, fibromyalgia, or chronic pelvic pain may help greatly in the management of these patients.

Evaluation for complications should occur at each office visit, even in patients without a history of mesh-related complications. Some complications, such as mesh exposure and dyspareunia, may manifest 8 to 10 years after insertion because they are increased with vaginal atrophy. The surgeon should consider following all patients with prior mesh implantation.

Physical Examination

Physical examination in patients presenting with mesh complications should focus on abnormalities whose treatment would relieve the symptoms. For example, **extrusion of mesh or permanent suture material into the vagina or through skin incisions, wound separation, hematoma, or abscesses can be addressed immediately and likely be completely reversed.** Physical examination greatly aids diagnosis of urinary obstruction after mid-urethral sling. The presence of urethral mobility suggests symptoms will resolve after a course of self-catheterization, whereas a highly suspended and fixed urethra suggests placement under tension and may require revision. This is in contrast to pain complications, which sometimes cannot be reversed, even with complete removal of mesh. Findings of alterations in pain processing such as allodynia or hyperalgesia should trigger immediate treatment or referral if all options have been exhausted.

Exposure is not a necessary component of mesh complications; complications can occur even in the absence of exposure and should be treated as separate issues in most cases. Mesh may be

Figure 85-5. Voiding cystourethrogram demonstrates narrowing (arrow) in a patient with lower urinary tract symptoms after mid-urethral sling placement.

palpable without exposure in cases of folding or shrinkage beneath the vaginal surface that can be identified on physical examination as palpation of tense cords or bands. Infiltration of mesh into the vaginal epithelium may appear indurated and tender to palpation. This finding should trigger repeated examinations because it may represent the beginning stages of erosion or exposure.

Diagnostic Studies

Additional imaging studies or diagnostic procedures may be warranted based on physical examination findings. Cystoscopy, vaginography, or colonoscopy can be used to identify mesh extrusion in the urethra or bladder, vagina, or colon. A voiding cystourethrogram can identify the location of anatomic obstruction (Fig. 85-5).

Video-urodynamics can aid in diagnosing patients presenting with urinary incontinence and voiding dysfunction by providing information on the level of obstruction, storage dysfunction, and the presence of stress incontinence. Ultrasonography, computed tomography, and magnetic resonance imaging may be used to identify collections such as hematoma or abscesses (Fig. 85-6). Stone formation in the lower urinary tract should raise suspicion for underlying mesh penetration.

Ultrasound is a useful tool to identify mesh location and depth of penetration (Fig. 85-7). It is sometimes necessary to identify mesh location preoperatively in cases where patients present without prior operative records, the procedure type is unknown, or multiple prior revisions are present. Preoperative evaluation can assist greatly in surgical planning and patient counseling in these cases. Similarly, ultrasonography can clearly demonstrate mesh penetration through the periurethral fascia under the urethral mucosa, a finding that cannot be appreciated by cystoscopy.

Figure 85-6. Magnetic resonance imaging identifies mesh (arrows) in a patient with pain after sacrocolpopexy.

Diagnosis

The use of standardized nomenclature has been encouraged for evaluation of mesh exposure (Skala et al, 2011). Clear documentation facilitates monitoring of symptoms over time as well as communication between physicians in cases of referral (Table 85-1) (Haylen et al, 2011). The International Continence Society and the International Urogynecologic Association recommend documenting complications by time of presentation, symptom severity, and presence of associated symptoms.

TREATMENT OF MESH COMPLICATIONS

Expectant Management and Counseling

There is a place for expectant management of mesh complications. The decision to proceed with expectant management should take into consideration the time since mesh placement, degree of symptoms, organ systems affected, and patient satisfaction. Patients who elect for expectant management must be appropriately counseled regarding treatment options and offered realistic expectations regarding anticipated improvement. A patient with asymptomatic mesh exposure without pain or pelvic organ dysfunction is an

TABLE 85-1 Suggested Terminology for Complications Related to the Use of Mesh

TERMINOLOGY	DEFINITION
Complication	Morbid process not part of original surgery
Contraction	Size reduction
Prominence	Parts project beyond a surface
Penetration	Enters
Separation	Physically disconnected
Exposure	Displaying or revealing
Extrusion	Gradual passage out of body
Perforation	Abnormal opening into hollow organ
Dehiscence	Gaping along natural or sutured lines

Modified from Haylen BT, Freeman RM, Swift SE, et al. An International Urogynecological Association (IUGA)/International Continence Society (ICS) joint terminology and classification of the complications related directly to the insertion of prosthesis (meshes, implants, tapes) and grafts in female pelvic floor surgery. *Int Urogynecol J Pelvic Floor Dysfunct* 2011;22:3–15.

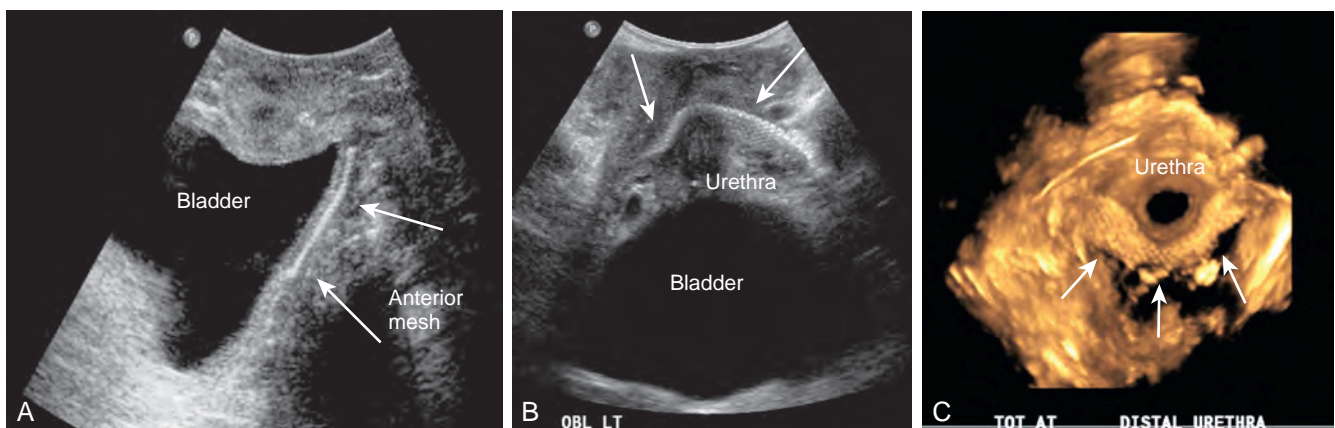

Figure 85-7. Translabial ultrasonography. A, Anterior vaginal synthetic graft (arrows), two-dimensional sagittal view. B, Mid-urethral synthetic sling (arrows), two-dimensional oblique view. C, Mid-urethral synthetic sling, no penetration of periurethral fascia (arrows), three-dimensional reconstruction.

example of an appropriate candidate for expectant management. These patients may present at any time from the immediate to delayed postoperative period, including decades later. However, the etiology of exposure and contributing factors depend significantly on time since placement. Immediate exposure suggests wound separation directly, whereas late presentation suggests a chronic process. In contrast, patients may present in the delayed postoperative period during which time weakened vaginal epithelium, inflammation, mesh shrinkage, and improper placement all may contribute to new diagnosis of exposure. This diagnosis can be particularly frustrating for physicians and patients who were reassured by lack of exposure at the first postoperative visit.

Medical Management

If an infectious component of mesh exposure is suspected, treatment with antibiotics is reasonable, with the expectation that persistent infection and exposure resistant to medications may require surgical excision of exposed portions, or more, to prevent further deterioration. Clindamycin and metronidazole are commonly used antibiotics for vaginal exposure. **If tissue atrophy is suspected, initiating vaginal estrogen can combat this process** and has been successful in reversing some atrophic findings (Vaccaro et al, 2013).

Medical management of pain symptoms is appropriate in select cases. Etiologies of pain such as urinary or fecal obstruction, hematoma, and abscess should be ruled out or treated appropriately. Drainage may be required for abscesses that do not respond to antibiotic therapy (Rafii et al, 2006; Ugurlucan et al, 2013). Residual pain may be treated with consultation with a pain specialist as needed. Pain out of proportion to physical examination, pain that fails medical management, or pain that persists past the postoperative period should be addressed promptly, and surgeons should be prepared to discuss additional treatment options. Pelvic floor physical therapy is appropriate for patients with pain, multicompartiment organ dysfunction, scar tissue, or preexisting pain syndromes. **Surgical removal of mesh in cases of severe refractory pain may improve symptoms in most patients** (Tijdink et al, 2011).

Surgical Management

Patients with persistent urinary retention may be offered surgical urethrolisis. This procedure can be performed through vaginal incisions, where the urethra is circumferentially freed from the anterior vaginal wall and pubic bone. Interposition with tissue flaps such as Martius labial flaps can be used to decrease recurrence. Outcome is difficult to predict, and voiding pressure/flow studies may be unnecessary before discussing intervention for obstruction (Winters et al, 2012). Improvement in obstruction can be achieved in 80% of patients after urethrolisis (Nitti and Raz, 1994), although many have residual urgency symptoms (Starkman et al, 2008).

Patients with pelvic organ dysfunction in the absence of pain or infection are candidates for partial mesh excision. This strategy is also an option for carefully selected patients with recurrent exposures who have failed conservative management. These patients must be aware that infection in this setting may not be limited to exposed segments alone, and they remain at risk for exposure of remaining mesh. The decision to proceed with complete excision is a difficult one, especially in patients whose prolapse and incontinence symptoms have been relieved. For this reason, we encourage careful patient selection, thorough counseling, and expectant management. Early removal may completely reverse symptoms (El-Nashar et al, 2013). Multiple failed attempts at partial excisions can be frustrating for the patient and the surgeon and contribute to low patient satisfaction. The surgeon also must consider that complete removal is more challenging when a patient has undergone prior partial excisions.

Complete excision of pelvic reconstruction mesh has been described (Fig. 85-8). In cases where mesh extends to suprapubic or thigh skin, marking puncture sites preoperatively at the location of patient discomfort may facilitate identification while the patient

is under anesthesia. Mesh size can be significantly smaller than when initially placed, making intraoperative identification difficult without external markings. **Armed products are among the most surgically challenging because of mesh quantity and the anatomic structures traversed, and referral to a surgeon with extensive experience with these procedures is recommended.** Removal of mid-urethral slings should begin with inspection and palpation of the anterior vaginal wall.

For **removal of retropubic slings**, an incision is made horizontally across the sling, with care not to incise the sling completely. The central incision should be carried to the sulci laterally where bilateral vertical incisions are made to facilitate entry into the retropubic space. Alternatively, lateral incisions can be made in the anterior vaginal wall. The sling is isolated from the vaginal wall and marked with a permanent suture. This is repeated on the contralateral side. A transverse incision is made in the anterior vaginal wall across the sling, with care not to incise the sling. When the midportion of the sling is visualized, it can be transected in the midline, and the lateral portions can be held with clamps or sutures for countertraction during dissection. Infiltrated or eroded vaginal wall should be excised. Starting with the central free portion, the sling arm can be dissected laterally until the retropubic space is reached. Using a curved scissor, the retropubic endopelvic fascia is sharply entered at the location of the sling arm. At this juncture, the medial portion must be dissected from the perivesical tissue, and the anterior portion must be dissected from the posterior pubic symphysis. This portion of the dissection is often very challenging and may require sharp tools for complete removal such as periosteal elevators used in orthopedic surgery. When the mesh arm is released from the bone and perivesical tissues, gentle traction should reveal the location of attachment to the anterior abdominal wall (presumably at or near the site of preoperative marking). A skin incision is made, and the subcutaneous tissue is incised to reveal the mesh, which is grasped with a clamp for retraction. The fascia is perforated sharply where the mesh traverses it. The entire sling arm should be free and can be removed. The same procedure is repeated for the opposite arm.

Removal of mid-urethral slings with transobturator arms begins similarly (Reynolds et al, 2012). When the midportion of the sling is released to the lateral incisions, the obturator fascia and obturator internus must be perforated and the mesh freed from its attachments circumferentially. The mesh must be dissected off the pubic bone, obturator membrane, and obturator externus. Gentle traction should reveal the location of the mesh as it traverses the adductor fossa toward the lateral labial or medial thigh exit site. The skin can be incised to reveal the adductor fascia and the gracilis and adductor longus muscles beneath. The mesh is transferred through the adductor fossa and subsequently removed. These steps are repeated on the opposite side.

Removal of vaginal prolapse mesh requires dissection of a larger portion of vaginal wall. Incision planning depends on the location and size of mesh, location and number of vaginal exposures, and plans for reconstruction after mesh removal. For removal of armed anterior vaginal mesh, a vertical incision is made in the anterior vaginal wall. Dissection is carried out laterally to the perivesical space to isolate the anterior mesh arms. The posterior arms are carefully dissected to the sacrospinous ligament attachments. During the process of mesh dissection from the sacrospinous ligament, care should be taken not to injure branches of the uterine artery because this can result in significant blood loss that is difficult to control. The pudendal nerve and lumbosacral nerve plexus also may be in the area of dissection in these cases and are at risk for injury. If anterior vaginal mesh is to be removed concurrently with a mid-urethral sling, an inverted-U incision is creased after removal of the mid-urethral sling, and the lateral incisions are carried to the vaginal cuff or uterus. This technique allows mobilization of the flaps for a tension-free closure. Using gentle traction, the vaginal wall and bladder can be separated from the underlying mesh.

Removal of isolated arms in patients with prior revisions is significantly more challenging because no central intact portion can be tractioned to identify the location of lateral arms. Large defects

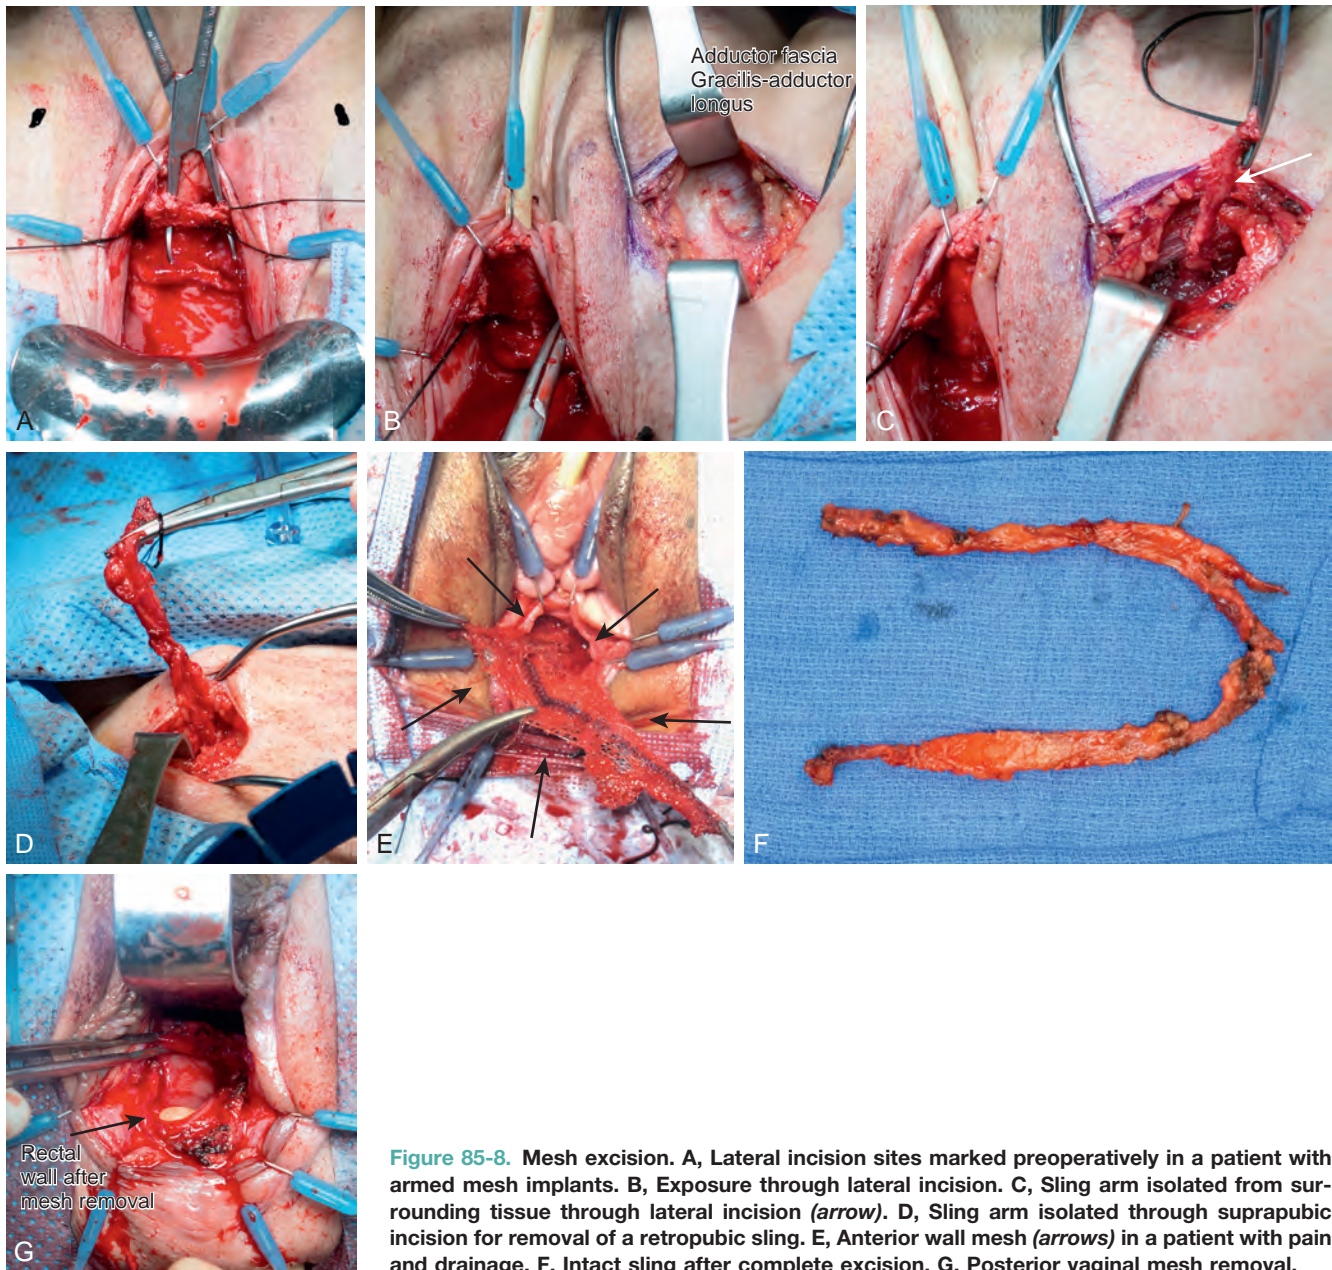

Figure 85-8. Mesh excision. A, Lateral incision sites marked preoperatively in a patient with armed mesh implants. B, Exposure through lateral incision. C, Sling arm isolated from surrounding tissue through lateral incision (arrow). D, Sling arm isolated through suprapubic incision for removal of a retropubic sling. may remain after mesh removal, especially after excision of exposed anterior vaginal mesh. These cases may require tissue flaps from the vaginal cuff or labia or other advanced pelvic reconstruction to repair defects without resultant vaginal stenosis. Pubovaginal slings of nonsynthetic tissue may be used for recurrent stress urinary incontinence (Shah et al, 2013).

Alternative Therapy

Alternative management strategies may be appropriate for patients with complications of mesh procedures. Acupuncture, botulinum toxin, and pelvic floor physical therapy have been used in the management of pelvic floor dysfunction and may be used in patients with a history of pelvic reconstructive surgery (Herderschee et al, 2013). Concurrent management with chronic pain specialists, gastroenterologists, or other specialists may assist with symptom control and patient satisfaction while the surgeon pursues evaluation and treatment.

Evaluation of recurrent prolapse or incontinence symptoms should not be undertaken until all complications have been addressed. Excision of mesh used in pelvic reconstructive surgery should not be delayed for fear of recurrent symptoms. Large series demonstrate a 30% to 50% incontinence risk after sling excision, and short-term data suggest only 20% of anterior compartment prolapse recurs after mesh removal (Marcus-Braun and von Theobald, 2010; Nakamura et al, 2013). The suggested explanation is that fibrotic tissue is at least as durable as traditional colporrhaphy alone.

CONCLUSION

Surgeons who perform mesh placement should strive to be competent with treatment of mesh complications and surgical removal. Complications of mesh used in the treatment of incontinence and prolapse are greater in frequency and morbidity than previously

described. Although some of these are mild and easily treated, some are not completely reversible. Estimates of frequency of complications are likely to increase as more patients undergo mesh-augmented surgery and longer term outcomes are reported.

The future is not a world without mesh; there remains a place for mesh-augmented incontinence and prolapse repair. Such procedures remain viable options for patients with poor tissue quality, patients who have failed prior nonaugmented repairs, and patients who have been appropriately counseled regarding the trade-off of possibly improved anatomic outcome against increased complication rates. Also, **current FDA investigation is focused on mesh placed vaginally for repair of anterior, posterior, or apical prolapse and not mesh placed abdominally for prolapse or mesh slings placed for urinary incontinence.** Urologic associations agree with this statement and continue to support mesh use for mid-urethral slings for the treatment of stress urinary incontinence (Dmochowski et al, 2010; American Urogynecologic Society and Society of Urodynamics, 2014). However, surgeons who are unfa-

miliar with removal of such devices and have limited experience in placement should be cautioned regarding their use and encouraged to refer to more experienced physicians when indicated.

Use of Injectable Agents in Female Stress Urinary Incontinence

Pathophysiology of Postprostatectomy Incontinence and the Use of Injectable Agents for Male Stress Urinary Incontinence

The quest for injectable agents for urinary incontinence started at the end of the 19th century when R. Gersuny (Gersuny, 1900) from Vienna suggested periurethral paraffin injection for urethral compression. In 1914, Howard Kelly (Kelly and Dumm, 1914) warned about the dangers of embolism after injection and pointed out that this treatment showed only temporary improvement of symptoms. In 1938, Murless first reported the injection of morrhuate sodium, a sclerosing agent synthesized from cod liver oil, into the anterior vaginal wall for treatment of stress urinary incontinence (SUI) (Murless, 1938). Of the 20 patients treated, 17 were cured or improved for at least 12 months. Sloughing of a segment of the anterior vaginal wall was seen in 12 patients, and of these, 75% were cured. Murless postulated that success was the result of contraction of the resulting scar of the anterior vaginal wall. Quackels (1955) reported on the injection of paraffin for incontinence after prostatectomy in 1955, and Sachse (1963), based on previous reports, injected a mineral oil preparation, granugenol oil, or Dondren, another sclerosing agent. He reported cures in 12 of 24 men who had undergone prostatectomy and 4 of 7 women. However, significant complications of pulmonary emboli and urethral sloughing were seen. With the last case report of distal ureteral stenosis after periurethral injection, it was recommended not to use sclerosing agents for incontinence (Bubanz et al, 1980).

Polytetrafluoroethylene (Teflon) paste was first introduced by Berg (1973) and then popularized by Politano and colleagues (1973). Shortliffe and coworkers (1989) published the first report on glutaraldehyde cross-linked (GAX) collagen, and Santarosa and Blaivas (1994) described the use of autologous fat in women with SUI. More recently, newer synthetic materials have been described that theoretically should improve efficacy, durability, and safety.

The ideal injectable agent should be easily injectable and should conserve its volume over time. It should also be biocompatible, nonantigenic, noncarcinogenic, and nonmigratory and should cause little or no inflammatory reaction (Kershen and Atala, 1999) or fibrotic ingrowth (Dmochowski and Appell, 2000). The components of the bulking agent should not separate or dissociate on injection, and, if the agent contains microcrystalline or micropolymeric components, they should be reasonably uniform spheres of particle sizes above 110 μm that are nonfragile and adhere to host tissue (Dmochowski and Appell, 2000). If unsuccessful, the treatment should not interfere with subsequent surgical intervention. To date, no substance has met all of these requirements.

Over the past 35 years there has been an evolution of injectable agents, and diverse types have been tested. In the late 1990s, injection therapy was the most commonly performed anti-incontinence procedure in women with SUI, at a rate of 3649 procedures per 100,000 women (Nygaard et al, 2004). By 2007 the rate had fallen to 2236 procedures per 100,000 (Rogo-Gupta et al, 2013). Reasons

Use of Injectables for Incontinence after Urinary Diversion

for the decline in numbers may be the less-than-optimal results, especially in the long term, and the availability of other minimally invasive options (Kong and Vasavada, 2009). Box 86-1 lists the agents that are discussed in this chapter. Most are bulking agents, but recently the injection of autologous stem cells for sphincter enhancement and implantable balloons that compress the urethra have been introduced.

The evidence for and the clinical use of injectable agents for SUI in women and men are reviewed in this chapter.

USE OF INJECTABLE AGENTS IN FEMALE STRESS URINARY INCONTINENCE

Pathophysiology of Stress Urinary Incontinence and the Role of Injectable Agents

The goal of injectables is to augment or restore urethral mucosal coaptation and its “hermetic seal effect” contribution to the continence mechanism (Appell and Winters, 2007) and to maintain coaptation during periods of increased abdominal pressure (Reynolds and Dmochowski, 2012). It is generally thought that these agents improve intrinsic sphincter function, although the exact mechanism has not been defined (Smith et al, 2009). Bulking agents such as collagen have been reported (McGuire and Appell, 1994; Monga et al, 1995) to augment urethral mucosa and improve coaptation and intrinsic sphincter function, as evidenced by an increase in post-treatment abdominal leak pressure (Herschorn et al, 1992; Richardson et al, 1995; Winters and Appell, 1995). Bulking agents do not usually obstruct voiding after the initial post-treatment period (Monga et al, 1995). Monga and coworkers (1995) showed that successfully treated patients have an increased area and pressure transmission ratio in the first quarter of the urethra. They suggested that placement of the injectable at the bladder neck or proximal urethra prevents bladder neck opening under stress, although this is controversial. Proper placement of the injectable, possibly just below the bladder neck, rather than actual quantity of the agent (Khullar et al, 1997) improves intrinsic sphincter dysfunction (ISD).

Patient Selection, Indications, and Contraindications

Injectable agents are one of the many treatment options for SUI. Although initially it was thought that these agents would be most effective in patients with ISD alone, multiple reports have shown clinical efficacy in patients with hypermobility (Herschorn et al, 1996; Steele et al, 2000; Bent et al, 2001a; Lose et al, 2010). Injectable agents may provide a rapid response for some patients and are an option for those who do not wish to undergo more

BOX 86-1 Types of Injectable Agents for Stress Urinary Incontinence**BIOLOGIC AGENTS****Bulking Agents**

No longer used: Homologous: bovine collagen (Contigen), porcine collagen (Permacol)

No longer used: Autologous fat

Cell-Based Therapy

Autologous muscle-derived stem cells (MDSCs), adipose tissue-derived stem cells (ADSCs)

Minced autologous striated muscle

SYNTHETIC AGENTS

Currently used: Carbon-coated zirconium beads (Durasphere), polydimethylsiloxane (Macroplastique), dextranomer hyaluronic acid (Deflux), polyacrylamide hydrogel (Bulkamid), calcium hydroxylapatite (Coaptite)

No longer used: Polytetrafluoroethylene (Teflon), ethylene vinyl alcohol (Tegress)

BALLOONS

Currently used: Adjustable balloons (ACT, ProACT)

No longer used: Microballoons (UroVive)

invasive procedures. However, the patient must understand that efficacy and duration are inferior to surgery and that follow-up injections may be required. Other possible indications include elderly patients, those with high anesthetic risk, or those willing to accept an improvement rather than cure of their SUI symptoms (Appell et al, 2012). Other considerations may include patients who cannot stop anticoagulation, desire nonsurgical therapy using only local anesthesia, desire more children, have mild persistent SUI after an SUI procedure, have SUI and poor bladder emptying, or have mild SUI associated with exercise (Cespedes and Serkin, 2009).

Detrusor overactivity should be treated before injection because results may be compromised (Herschorn et al, 1996). Severe urethral scarring from radiation or surgery may affect mucosal pliability by preventing bulking and retention of the injectable in the urethra.

Contraindications include active urinary infection and hypersensitivity to the injectable material.

Workup

Patients who may be candidates for injectable agents should undergo a diagnostic evaluation to confirm the diagnosis in a similar fashion to other patients with SUI. A focused history to characterize the chief complaint including the frequency, severity, and degree of bother should be done. An assessment of other urinary symptoms should be completed and the desire for treatment should be ascertained. Helpful tools include various validated symptom and quality-of-life questionnaires and frequency-volume charts (Appell et al, 2012; Staskin et al, 2013).

Physical Examination

The physical examination should provide information about the cause of the lower urinary tract symptoms and suggest additional management options. The general examination should include an abdominal examination to evaluate the skin, surgical incisions, and the presence of any hernias or abdominal masses, including a full bladder. Pelvic and perineal examination should be performed.

Pelvic Examination

The patient is placed in the lithotomy position. The external genitalia should be examined for dermatologic lesions and inflammatory conditions. The internal genitalia should be examined for estrogen deficiency, urine or abnormal vaginal discharge, pelvic organ prolapse, and abnormal pelvic masses. The poorly estrogenized vaginal wall has a thinned epithelium with loss of transverse rugae, which are normally present in its lower two thirds (Fantl et al, 1994). The patient should be examined with a comfortably full bladder to assess stress leakage and, if necessary, with an empty bladder to assess other pelvic organ prolapse and masses.

Because incontinence (or pelvic organ prolapse) may not be evident, or its full extent demonstrated, in the dorsal lithotomy position, it has been recommended that the patient be examined in the semiupright or even upright position (Walters and Karram, 1992). A systematic examination of the vaginal walls and perineum should also be done. (For details, please refer to the chapter on pelvic organ prolapse.)

Urethral mobility can be observed with the patient straining or by the cotton-swab or Q-tip test (Crystle et al, 1971). The angles of deflection of the Q-tip at rest and with straining are measured with a goniometer. Hypermobility is defined as a maximum strain axis of more than 30 degrees from the horizontal. Urethral axis testing does not diagnose any form of incontinence because continent women may demonstrate rotational descent of the urethra (Fantl et al, 1986) and incontinent women may have no descent. Although this method has been shown to be reproducible (Fantl et al, 1986), it has not been compared with other radiologic methods. However, it may be helpful in assessing the degree of hypermobility.

If the patient has a fixed nonmobile urethra, especially if there has been previous SUI surgery, and leaks occur with coughing and/or straining, most likely the patient has ISD as the predominant cause of the SUI. However, if hypermobility is present, the relative contribution of the causes (ISD vs. anatomic support) cannot be ascertained clinically.

Additional Testing

The initial evaluation of urinary incontinence in women includes a history, physical examination, urinalysis, and measurement of post-void residual (PVR) urine (Abrams et al, 2010). The basic evaluation may be satisfactory for proceeding with treatment, including surgery, for patients with straightforward stress incontinence associated with hypermobility with normal PVR volume (Fantl et al, 1996). The indications for additional testing include an inability to make a definitive diagnosis based on symptoms and the initial evaluation; concomitant overactive bladder symptoms; prior lower urinary tract surgery (including failed anti-incontinence procedures); known or suspected neurologic disease affecting the bladder; negative stress test result; abnormal urinalysis findings such as hematuria or pyuria; abnormal PVR urine; beyond hymen and symptomatic pelvic prolapse; and dysfunctional voiding (Appell et al, 2012). Additional testing can include pad testing and/or voiding diary, urodynamic studies, cystoscopy, and imaging. The evaluation can be tailored to elucidate the patient's problem.

Urodynamic Studies

In the evaluation of the patient with SUI, urodynamic studies before interventional treatment are helpful in specific circumstances. These studies are used to confirm the diagnosis if the symptoms are confusing or complex and other problems are suspected, such as detrusor overactivity, urethral obstruction or voiding dysfunction, low bladder compliance, and/or impaired or absent detrusor contractility (Appell et al, 2012; National Institute for Health and Care Excellence [NICE], 2013). Urodynamic studies have also been recommended if there has been previous surgery for SUI or anterior compartment prolapse (NICE, 2013). Multichannel urodynamic studies are not recommended in patients with pure SUI diagnosed on history and physical examination (NICE, 2013; Lucas et al,

2014). There is also evidence that women with uncomplicated clinically demonstrable SUI whose surgery is determined by office evaluation alone have similar postoperative outcomes to patients who undergo office evaluation plus urodynamic studies (Nager et al, 2012). Similarly, in a randomized controlled trial (RCT) comparing SUI patients who had urodynamic findings discordant with symptoms, there were similar postoperative outcomes whether the patients had immediate surgery versus other tailored intervention determined by the urodynamic findings (van Leijssen et al, 2013). However, urodynamic testing was recommended before surgical intervention in all patients at the Fifth International Consultation on Incontinence (Rosier et al, 2013).

Because injectable agents are indicated for the ISD component of SUI, can urodynamic studies assess ISD? Two measures of urethral function have been used: maximum urethral closure pressure (MUCP) and abdominal leak point pressure (ALPP). MUCP of 20 cm H₂O or lower has been suggested as indicating clinically significant urethral weakness, but there is controversy regarding the diagnostic and predictive value of urethral pressure profilometry in characterizing ISD (Weber, 2001). Similarly an ALPP of 60 cm H₂O or lower was identified as an indicator of severe ISD (McGuire et al, 1993), but many studies have not confirmed the test's value in quantifying the degree of ISD (Koelbl et al, 2009). Previously, ALPP measurements of initially 65 cm H₂O or lower and then 100 cm H₂O or lower were used as indicators of ISD to justify the use of injectable agents (Appell and Winters, 2007). However, because ISD may be present in many patients with SUI with or without urethral hypermobility (Koelbl et al, 2009, 2013), the specific value of either MUCP or ALPP may be of no importance in the clinical decision about the use of injectables. As with other patients with SUI who opt for interventional therapy, urodynamic studies may be helpful for the aforementioned reasons.

Cystoscopy

Routine cystoscopy is not recommended for the evaluation of SUI. However, it is indicated for the evaluation of incontinent patients

who have sterile hematuria or pyuria; urgency incontinence to rule out other pathologies (e.g., bladder tumor, interstitial cystitis); recurrent or iatrogenic incontinence when surgery is indicated or planned; or vesicovaginal fistula or extraurethral incontinence (Tubaro et al, 2009), or when urodynamic studies fail to duplicate symptoms of incontinence (Fantl et al, 1996). Furthermore, **preinjection cystoscopy is helpful to make sure that there are no adverse factors or unexpected findings that may prevent or compromise the injection procedure such as extensive urethral scarring from previous surgery, radiation, trauma, foreign bodies, or urethral diverticula.**

Injection Techniques

The materials can be administered using local anesthesia with cystoscopic control as an outpatient procedure. Both the **periurethral** and **transurethral** methods have been done to implant the agent within the urethral wall, preferably into the submucosa or lamina propria. It is thought that the implant should be positioned at the bladder neck or proximal urethra. Different sites can be chosen, such as the 3 and 9 o'clock or 4 and 8 o'clock positions. The needle size depends on the viscosity of the injectable. Preoperative and postoperative antibiotics are frequently administered. The technique for injection is shown in Figures 86-1 and 86-2. Additional bilateral periurethral infiltration of 2 to 3 mL of 1% or 2% aqueous lidocaine injected lateral to the urethra may improve patient comfort. The goal with current injectables is to create mucosal apposition at the end of treatment.

Periurethral Technique

The patient is placed in the lithotomy position and prepared and draped in the usual sterile fashion. Topical 2% urethral lidocaine jelly is instilled into the meatus. Perimeatal blebs are raised with 1% or 2% aqueous lidocaine at the 3 and 9 or 4 and 8 o'clock positions approximately 3 to 4 mm lateral to the urethral meatus with a 25-gauge needle. A 20-Fr urethroscope with a 30-degree telescope is inserted into the urethra. The periurethral needle is

Figure 86-1. Periurethral collagen injection. The 20-Fr cystoscope with a 30-degree lens is positioned in the urethra while the substance is injected into the bladder neck region. introduced and advanced parallel to the endoscope sheath until its position can be seen cystoscopically just below the bladder neck within the mucosa. The surgeon can hold the cystoscope in one hand and advance the needle with the other. Care must be taken to prevent the needle from getting too close to or entering the urethral lumen because rupture of the mucosa and extravasation will occur. Rocking the needle will confirm the position of the tip. If penetration of the mucosa occurs, the needle should be removed and repositioned. The substance is injected either unilaterally or bilaterally to create the appearance of “prostatic” lobes (Fig. 86-3). Transvaginal injection with the needle placed through the biopsy port of an ultrasound probe has also been described (Appell, 1996).

An 18-gauge bent-tipped needle has been designed for the periurethral approach for placement of Durasphere beads within the proper plane (Appell and Winters, 2007).

Transurethral Techniques

With Cystoscopic Monitoring. The implant can also be injected transurethral through the cystoscope with specially designed injection needles or with other devices that do not necessitate cystoscopy. In this approach a 0-, 12-, or 30-degree lens may be used. Various cystoscope sheaths are available, but one with a flat rather than a beaked end will prevent the needle from penetrating the urethra proximal to the view from the lens. Endoscopic instrument companies have an array of equipment designed for transurethral injections. The material can be injected through a semirigid needle that is advanced through a working element or a flexible needle that is advanced by the surgeon. Both have 22-gauge tips that are about 1 cm long.

The patient is prepared in the same fashion as for the periurethral approach. Topical urethral lidocaine jelly as well as aqueous lidocaine injected periurethrally can be used. The injection needle is inserted into the urethra at a 30- to 45-degree angle and advanced proximally in the submucosal region under the surface of the mucosa. The point of penetration of the urethra has to be at a distance below the bladder neck of more than the length of the needle to prevent extravasation of the substance into the bladder. Injections can be given at the 3-, 6-, and 9-o'clock positions until mucosal apposition is achieved. The cystoscope should not be advanced through the bulked up urethra and bladder neck to avoid compressing or causing extravasation of the injected material.

Because of the high viscosity of Macroplastique, injections of this material require the use of a ratcheted injection gun (Fig. 86-4). The injection needle is 7 Fr with a 10-mm 18-gauge needle tip.

Polyacrylamide hydrogel (PAHG; Bulkamid) is provided in 1-mL syringes with a 12-cm 23-gauge needle and is injected via a short 0-degree urethroscope and plastic sheath (Fig. 86-5).

The periurethral and transurethral approaches for collagen were compared first by Faerber and colleagues (1998), who reported no significant difference in success rates and numbers of injections required in 24 patients with transurethral treatment versus 21 with a periurethral approach. However, significantly more collagen was required for the periurethral approach. Schulz and coworkers (2004) reported similar findings in 40 women randomly assigned to either technique. There was no difference in short-term success rate, but the 20 women assigned to the periurethral approach required more collagen than those assigned to the transurethral approach. Furthermore, the Cochrane review

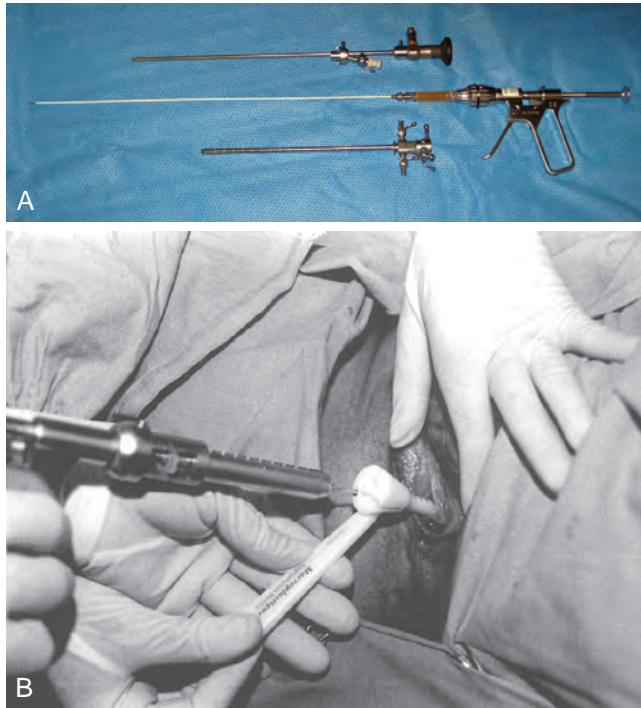

Figure 86-4. A, Silicone macroparticle injection gun. The injection needle is 7 Fr with a 10-mm, 18-gauge needle tip. B, The implantation procedure. The bulking agent is injected through the device using the injection gun and a rigid needle. (From Tamanini JT, D'Ancona CA, Netto NR Jr. Treatment of intrinsic sphincter deficiency using the Macroplastique Implantation System: two-year follow-up. *J Endourol* 2004;18[9]:906–11.)

Figure 86-5. Bulkamid urethral injection system. Bulkamid is injected transurethraly with a short 0-degree telescope through a plastic sheath. The sheath with injection needle port rotates to allow injection of the agent at different sites. (From Sokol ER, Karram MM, Dmochowski R. Efficacy and safety of polyacrylamide hydrogel for the treatment of female stress incontinence: a randomized, prospective, multicenter North American study. *J Urol* 192[3]:843–9.)

concluded that there are insufficient data to determine whether the transurethral is superior to the periurethral approach and whether mid-urethral injection offers any benefit over bladder neck injection (Kirchin et al, 2012). The transurethral approach is now more commonly reported than the periurethral approach.

Regarding the distribution of the injected agent, circumferential dispersal around the urethra appears to correlate with a better outcome as determined in studies using three-dimensional ultrasound (Radley et al, 2001; Defreitas et al, 2003; Poon et al, 2005; Hegde et al, 2013).

Without Cystoscopic Monitoring. A handheld device that allows the operator to inject Macroplastique transurethraly without cystoscopy was introduced by Henalla and colleagues (2000) in a multicenter trial of 40 patients (see Fig. 86-4B). Device efficacy and acceptability were rated highly by the surgeons at 92.5% and 95%, respectively, and at 3 months 74.3% of patients had a good outcome. Twelve-month outcomes in a cohort of 21 patients who had Macroplastique injections administered with this device were reported by Tamanini and coworkers (2003); 57.1% of patients considered themselves cured, 19% improved, and 23.8% failed. Two-years outcomes showed some deterioration in results, with 47% cured, 14.3% improved, and 38.1% failed (Tamanini et al, 2004).

Periprocedure Care

Although randomized trials have not been done, prophylactic antibiotics with a fluoroquinolone or trimethoprim-sulfamethoxazole (TMP-SMX) for 24 hours or less can be recommended (Wolf et al, 2008). An additional 2 to 3 days has also been suggested (Appell and Winters, 2007).

After the injection the patient is asked to cough or strain in the supine and then the upright position. If leakage still occurs, more agent may be given. If no leakage is seen, the procedure may be terminated. The patient then voids and can be discharged. Urinary retention can be treated by insertion of a fine Foley catheter (12 to 14 Fr or smaller) overnight or intermittent catheterization. Although not specifically reported, an indwelling Foley catheter may cause molding of the agent and lead to early failure, so long-term catheterization should be avoided.

Reinjections

The minimum timing for reinjections is variable and depends on the agent. Although bovine GAX collagen (Contigen) could be reinjected within 7 days, most clinicians have waited 4 weeks or longer to assess response of the urethra and the need for reinjection (Appell and Winters, 2007). Silicone microimplant (Macroplastique) injections can be repeated after 12 weeks (see <http://www.uroplasty.com/Uroplasty/view/files/pdf/4171.pdf>). Carbon-coated zirconium beads (Durasphere) can be reinjected after a minimum of 7 days (Lightner et al, 2001) and calcium hydroxylapatite (CaHA; Coaptite) after 1 month or less (Mayer et al, 2007). PAHG (Bulkamid) has been reinjected at 1 to 2 months (Tooze-Hobson et al, 2012; Sokol et al, 2014).

Pitfalls in Reported Study Results of Durability

A number of pitfalls in reporting of injectable studies can lead to inflated success rates. Because injectable agents can be repeated if the treatment is not a success, authors should specify whether the time point of reporting is after all treatments have been completed or whether it is from baseline. If durability is reported after all injections have been administered, then an accurate picture of duration of efficacy can be conveyed. A Kaplan-Meier curve of efficacy has been useful in showing what happens to patients' continence outcome over time (Herschorn and Radomski, 1997; Lightner et al, 2001). Nevertheless, some studies report duration of results from initial treatment (Richardson et al, 1995) or do not specify (Monga et al, 1995). This may result in overestimation of success because failed treatments are repeated and counted as successes within the follow-up period. Another pitfall is reporting success rates for cohorts of patients followed for the long term rather than on all patients treated from the start (Stenberg et al, 2003). If the patients in whom treatment has failed and those who have been lost to follow-up are not included in the denominator, the success rate will be higher.

TABLE 86-1 Stamey Incontinence Grading System

GRADE	DESCRIPTION
0	Continent
1	Patient loses urine with sudden increases in abdominal pressure but not when supine
2	Patient loses urine with physical stress (walking; changing from a reclining to a standing position; sitting up in bed)
3	Patient has total incontinence; urine loss unrelated to physical activity and/or position

Another problem encountered in clinical studies, especially longer-term studies, is accounting for missing data from patients who dropped out. One way of handling this is to impute or assign a value based on a previous result. A standard method is last observation carried forward (LOCF). Although this may solve the problem of missing data, it may bias the study in favor of a good outcome. For example, in the 2-year follow-up study of Bulkamid, [Tooze-Hobson and coworkers \(2012\)](#) reported a responder rate of 64% in 116 women. However, there were 135 women treated at the beginning of the study and only 86 were available for the 24-month follow-up. If one calculates the number of responders in the 86 evaluable patients using the 64% responder rate and then uses that number to calculate the percentage in the 135 patients, the success rate then becomes 41%, substantially less than that reported. In view of this potential bias, other, more robust methods than LOCF are available to provide for missing data ([Siddiqui et al, 2009](#)).

Outcome Assessment in Bulking Agent Clinical Trials by the U.S. Food and Drug Administration

The Stamey grading system (0 to 3) ([Stamey, 1979](#)) ([Table 86-1](#)) for SUI has been recommended as the primary outcome measure by the U.S. Food and Drug Administration (FDA) since the original U.S. collagen trial ([McGuire and Appell, 1994](#)). Although the scale has been used extensively, there is little evidence that it is as valid or reliable as other measures such as voiding diaries, pad tests, and leak point measurements ([Payne et al, 2009](#)).

Systematic Reviews and Clinical Practice Guidelines on the Use of Injectable Agents for Women with Stress Urinary Incontinence

The Cochrane Database of Systematic Reviews published an update review of injectable agents in women in 2012 ([Kirchin et al, 2012](#)). The authors reviewed the findings of 14 trials including 2004 women and concluded that the lack of long-term follow-up and health economic data means that at present, injection therapy cannot be recommended as an alternative therapy for women fit for other surgical procedures. The evidence does not support the usefulness of injection therapy as a first-line option. However, it may be a useful option for short-term symptomatic relief for women with comorbidities that preclude anesthesia, at least for a 12-month period. Two or three injections are likely to be required for achievement of a satisfactory result.

Injection therapy was also reviewed at the Fifth International Consultation on Urinary Incontinence ([Dmochowski et al, 2013](#)). The authors concluded that bulking agents provide an option in the management of women with stress incontinence. Although efficacy may diminish over time and may be inferior to that of surgical treatment, the overall complication rate is relatively low.

The American Urological Association (AUA) clinical practice guidelines support the use of injectable agents for patients who

do not wish to undergo more invasive surgery and who understand that both efficacy and duration are inferior to those after surgery. Other groups include the elderly, those who are at high anesthetic risk, and those willing to accept an improvement in their incontinence without necessarily achieving dryness ([Appell et al, 2012](#)). The European Association of Urology guidelines also mention that bulking agents may provide short-term improvement and require repeat injections. They are less effective than surgical options but have fewer adverse effects ([Lucas et al, 2014](#)).

KEY POINTS: USE OF INJECTABLES IN FEMALE STRESS URINARY INCONTINENCE

- The ideal injectable that is biocompatible, nonantigenic, noncarcinogenic, and nonmigratory; causes little or no inflammatory reaction or fibrotic ingrowth; and retains efficacy over time has not yet been found.
- The goal of injectables is to augment or restore urethral mucosal coaptation and its hermetic seal effect and to maintain coaptation during periods of increased abdominal pressure.
- Although initially it was thought that these agents would be most effective in patients with nonhypermobile ISD alone, multiple reports have shown clinical efficacy in patients with hypermobility.
- Injectable agents may provide a rapid response for some patients and are an option for those who do not wish to undergo more invasive procedures. The efficacy and duration are inferior to those after surgery, and reinjections are frequently required. Other possible indications include elderly patients, those with high anesthetic risk, and those willing to accept an improvement in rather than cure of their SUI symptoms.
- The workup includes history and physical examination. Urodynamic studies may be helpful. Cystoscopy is helpful to rule out adverse factors such as scarring, foreign bodies, and diverticula that may prevent or compromise injections.
- Injectables are indicated for the ISD component of SUI. However, because ISD may be present in many patients with SUI with or without urethral hypermobility, the specific value of either the MUCP or ALPP may be of little importance in the clinical decision about the use of injectables.
- The results of periurethral and transurethral techniques are similar. Most reports now involve use of the transurethral technique.
- Perioperative antibiotics for 24 hours or less can be recommended.

Glutaraldehyde Cross-linked Bovine Collagen (Contigen)

Bovine collagen production was discontinued in 2010 with the development of biocompatible hyaluronic acid (HA) fillers for cosmetic soft-tissue augmentation ([Schwanke, 2010](#)). The HA is cross-linked chemically to prevent degradation and has tissue bulking properties ([Park et al, 2014](#)).

Until it was discontinued, GAX collagen was the most widely used and best-studied urethral injectable agent. It was the standard against which all new injectables were compared.

GAX collagen is a highly purified suspension of bovine collagen in normal saline containing at least 95% type I collagen and 1% to 5% type III collagen ([Remacle et al, 1990](#)). This cross-linking makes the GAX collagen resistant to the fibroblast-secreted collagenase. As a result of this, the GAX collagen is only very slightly resorbed. The implant causes little inflammatory reaction or granuloma formation and is colonized by host fibroblasts and blood vessels. It is not known to migrate. However, it does degrade over time with volume loss via absorption of the carrier medium ([Kershen and Atala, 1999](#)) and may be replaced by host collagen, to explain its persistence

(Keefe et al, 1992). For its antigenicity to be decreased, the GAX collagen is prepared by selective hydrolysis of the nonhelical amino- and carboxy-terminal groups (telopeptides) of the collagen molecule, which are the antigenic parts of the molecule (Remacle and Delaye, 1988).

All patients had to undergo a skin test into the volar aspect of the forearm 30 days before treatment. Approximately 3% of patients had a positive skin test reaction, with 70% showing the reaction within 3 days, indicating a preexisting sensitivity to bovine dermal collagen through dietary exposure. The remaining 30% did not respond until later, so a 4-week period was required (Keefe et al, 1992). A negative skin test result did not preclude development of a hypersensitivity reaction to subsequent treatment and, although infrequently used, a second skin test was recommended (Elson, 1989; Stothers and Goldenberg, 1998). Positive responders were excluded.

GAX collagen was injected transurethraly or periurethraly through a 22-gauge needle. It was supplied in syringes, which contained about 3 mL of collagen. Ordinarily one to three syringes were injected during each treatment.

Because more is known about this agent than any other to date, the results are outlined in the following section.

GAX Collagen Results. The results are shown in Table 86-2. The use of GAX collagen was first reported by Shortliffe and colleagues (1989), and since then numerous reports of its efficacy, safety, ease of administration, and relative lack of morbidity have appeared. Our original report, with short-term follow-up of 32 patients for 6 months (Herschorn et al, 1992), showed a cure and improvement rate of 90.3%. For longer-term results of more than 1 to 2 years, cure and improvement rates vary from 57% (Khullar et al, 1997) to 94% (Cross et al, 1998). Most patients need one or two treatment sessions with a mean of 5.6 to 15 mL of collagen. Winters and Appell (1995) reported a 50% rate of complete continence in a multicenter trial after 2 years. Corcos and Fournier (1999) reported 4-year follow-up with 40% improvement and 30% cure. The longest follow-up reported to date is from Gorton and coworkers (1999). They reported on 53 patients with at least 5 years after their last collagen injection. Only 14 (26%) had persistent improvement, and of these, 1 (2%) was completely dry. Because patients in any series are treated at different times and because durations of follow-up vary, a Kaplan-Meier curve is useful to display the persistence of a good result (Herschorn and Radomski, 1997). Figure 86-6 shows that the probability of remaining dry after the last collagen injection was 72% at 1 year, 57% at 2 years, and 45% at 3 years. A similar deterioration over time was reported by Gorton and coworkers (1999).

Multiple factors that may influence outcome have been reported. Previous incontinence surgery was identified by Eckford and Abrams (1991) as a favorable factor, but this was not supported by others (Herschorn et al, 1996). Preoperative detrusor overactivity may be an adverse factor (Herschorn et al, 1996; Smith et al, 1997). The degree of mucosal coaptation after injection as judged on cystoscopy was not found to correlate with long-term improvement (Kim et al, 1997). Elia and Bergman (1996) used perineal ultrasound to measure the location of the collagen deposit 3 months after the procedure. They reported that a positive outcome was more likely if collagen was located at a distance of 6 mm or less from the bladder neck. Defreitas and coworkers (2003) correlated a good outcome with circumferential distribution of collagen around the urethra. They performed three-dimensional transvaginal ultrasound in 46 patients at a median follow-up of 14 months and found that the 21 satisfied patients had a higher rate of circumferential distribution compared with the 25 unsatisfied patients. Regarding the technique and site of injection, the Cochrane review concluded that there are insufficient data to determine whether transurethral is superior to periurethral injection and whether mid-urethral offers any benefit over bladder neck injection (Kirchin et al, 2012).

Collagen and Hypermobility. The use of collagen for patients with hypermobility has been reported extensively. Moore and colleagues (1995) included patients with hypermobility. Faerber (1996) treated elderly patients with type 1 abnormality. In the

Figure 86-6. Durability: Kaplan-Meier curve showing durability of cure of incontinence after the last collagen injection in 78 patients. (From Herschorn S, Radomski SB. Collagen injections for genuine stress urinary incontinence: patient selection and durability. *Int Urogynecol J Pelvic Floor Dysfunct* 1997;8[1]:18-24.)

report by McGuire and Appell (1994), the results at longer than 1 year in women with ISD were similar to those in women with hypermobility, although there were far more women with ISD. Monga and coworkers (1995) included patients with hypermobility and found that cure rates were not reduced for women with up to 2.5 cm of movement. In our series of 181 patients there was no significant difference in outcome in patients with or without hypermobility (Herschorn and Radomski, 1997). Corcos and Fournier (1999) found no difference between patients with and without bladder neck hypermobility in their 4-year follow-up on 40 patients. Steele and colleagues (2000) found that urethral mobility did not significantly affect the success rate. Furthermore, 4 of 6 patients with urethral hypermobility were dry at the 6-month follow-up examination, whereas of the 19 women without hypermobility, only 32% remained dry. Bent and colleagues reported a 44% cure and improvement rate for 12 months in a cohort of 90 women with SUI and hypermobility (Bent et al, 2001a). They concluded, as have others, that collagen injection therapy is appropriate in women with hypermobility.

Collagen versus Surgery. Berman and Kreder (1997) found that after an average follow-up of 14.9 months after sling cystourethropexy, 71.4% of the patients were continent versus 26.7% of patients with collagen after 21.3 months. They analyzed associated costs and concluded that surgery was more cost-effective than collagen. In a multicenter prospective randomized trial, Corcos and colleagues (2005) reported a lower success rate of 53.1% in the collagen-treated patients versus 72.2% in the surgery group. However, general and disease-specific quality-of-life scores were similar, satisfaction was slightly higher in the surgery group, but complications were less frequent and severe with collagen. They concluded that collagen was a reasonable alternative to surgery. The follow-up was relatively short, and the study was done before the era of mid-urethral slings.

Collagen Complications. Treatment-related morbidity has been minimal. Common complications include transient urinary retention, which ranges in incidence from 1% to 21% (Herschorn et al, 1992; Winters and Appell, 1995; Appell and Winters, 2007) and can be managed with intermittent catheterization or short-term use of a Foley catheter. Urinary tract infection (UTI) occurs in 1% to 25% (Herschorn et al, 1992; Winters and Appell, 1995; Appell and Winters, 2007). De novo detrusor overactivity was reported in 11 of 28 elderly women (39%) treated by Khullar and coworkers (Khullar et al, 1997). Stothers and colleagues reported de novo urgency with urgency incontinence in 43 of 337 patients (12.8%), 21% of whom did not respond to anticholinergics

ISD, intrinsic sphincter deficiency.

(Stothers et al, 1998). Hematuria can occur in 2% of patients (Appell and Winters, 2007). Extravasation resolves quickly with flushing away of the dilute collagen suspension and sealing over of the small needle site.

Rare complications include periurethral abscess formation (Sweat and Lightner, 1999). Another is a reaction in the previously negative skin test site after a urethral collagen injection (Stothers and Goldenberg, 1998). This occurred in three patients (1.9%) and was associated with arthralgias in two. Mohr and colleagues (2013) reported a late-onset allergic reaction in two women at 3 and 6 weeks after treatment. Both required steroids, and one was hospitalized for 34 days. Hypersensitivity reactions have been reported before in dermatology (Elson, 1989), and two negative pretreatment skin tests have been suggested for prevention of such a reaction. The potential for hypersensitivity reactions is present because antibody production is stimulated by collagen injection (McClelland and Delustro, 1996).

Vesicovaginal fistula occurring after collagen injections for SUI in two women after cystectomy and neobladder was described by Pruthi and colleagues (2000). Carlin and Klutke (2000) reported a urethrovaginal fistula in a woman whose warfarin was not completely reversed. She had a postinjection hematoma, and ultimately a fistula to the vagina developed.

Currently Used Injectable Agents

Carbon-Coated Zirconium Beads (Durasphere and Durasphere EXP)

Durasphere consists of nonabsorbable pyrolytic carbon-coated zirconium beads suspended in a water-based polysaccharide carrier gel of 2.8% β -glucan (Lightner et al, 2001). Pyrolytic carbon has been used in medical devices such as heart valves. The bead size ranges from 212 to 500 μ m, which is larger than the threshold for particle size migration of 80 μ m (Malizia et al, 1984). It is nonantigenic, and no skin testing is required. The agent can be delivered through an 18-gauge needle via the transurethral or periurethral approach with cystoscopic monitoring. It is more viscous than collagen, so greater pressure is required for delivery into the tissues.

As a result of reported difficulty of injecting the agent, the beads were modified and made smaller. The bead sizes of Durasphere EXP now range from 90 to 212 μ m, still larger than the 80- μ m threshold for migration (Malizia et al, 1984).

Results. Published results for use of Durasphere are shown in Table 86-3. In the original multicenter randomized 235-patient clinical trial of Durasphere versus collagen, Lightner and colleagues (2001) reported a 12-month continence grade improvement rate of 76 of 115 (66.1%) in the Durasphere group versus 79 of 120 (65.8%) in the collagen group ($P = 1.000$). They also reported that at 1 year after their last treatment, 49 of 61 (80.3%) in the Durasphere group versus 47 of 68 (69.1%) in the collagen group had a

continence grade improvement ($P = .162$). Both injectables performed similarly. There was also no difference in the number of injections or pad weight test result. However, the injected initial and repeat injection volumes of Durasphere were significantly less than those of collagen. It is notable that in the 12-month result after the last injection, 45% (106 of 235) of the study patients were not accounted for.

In another randomized prospective trial of Durasphere versus collagen, Andersen (2002) reported that 80% (20 of 25) of Durasphere patients versus 61.9% (13 of 21) of collagen patients had a continence grade improvement ($P = .205$) after a mean of 2.6 and 2.8 years, respectively, after initial treatment. This is similar to the study of Lightner and colleagues (2001).

In a series of 13 women, Pannek and colleagues (2001) reported a decline in success from 76.9% at 6 months to 33% at 12 months. In contrast to Lightner and colleagues (2001), they demonstrated particle migration locally and to distant sites on follow-up plain radiographs. As a result of reported injection difficulties, Madjar and coworkers (2003) modified the technique by injecting local anesthetic into the mucosa to raise a circumferential bleb into which the Durasphere was injected. They reported results from 46 of 70 (65.7%) of patients. At a mean of 9.4 months, 65.2% of patients considered themselves to be cured or improved.

In a longer-term follow-up matched cohort study, Chrouser and colleagues (2004) reported initial success of 63% in both groups. With longer follow-up of 24 and 36 months, Durasphere was effective in 33% and 21%, whereas collagen was effective in 19% and 9%, respectively. The results in both groups were not significantly different. Sokol and coworkers (2008) tried to improve on the results of transurethral collagen by injecting additional periurethral Durasphere. However, they failed to show any benefit. After 6 months there was no difference in cure rates—33.3% in the combined versus 29.4% in the collagen alone group.

No study with Durasphere has shown a benefit over collagen.

Complications. In the multicenter randomized trial of Durasphere versus collagen, the adverse event profiles were similar with both agents (Lightner et al, 2001). However, more women had significantly more post-treatment urgency and acute retention with Durasphere versus collagen—24.7% and 16.9% versus 11.9% and 3.4%, respectively. Pelvic radiographs taken 1 and 2 years after injection showed stability of the bulking agents at the injection site. Pannek and associates (2001) did report particle migration. This was subsequently attributed to the high pressure necessary to inject the viscous material with large particles, resulting in material displacement into vascular or lymphatic spaces (Appell et al, 2006). Durasphere EXP with smaller particles is less likely to lead to this.

Other reported adverse events include urethral mucosal prolapse (Ghoniem and Khater, 2006), periurethral sterile abscess formation in 2.9% of a series of 135 patients (Madjar et al, 2006), or rarely a pseudoabscess found 5 years after injection (Berger and Morgan, 2012).

Silicone Microimplants (Macroplastique)

Silicone microimplants (Harriss et al, 1996) are solid polydimethylsiloxane (silicone rubber) particles suspended in a nonsilicone carrier gel that is absorbed by the reticuloendothelial system and excreted unchanged in the urine. Because 99% of the particles are between 100 μ m and 450 μ m in diameter, the likelihood of migration is low. Henly and coworkers (1995) demonstrated distant migration of small particles, less than 70 μ m, but no migration of particles greater than 100 μ m in diameter. Although there was a typical histiocytic and giant cell reaction within the injection site, there was no granuloma formation in response to the larger particles. Because the substance is quite viscous, it must be injected with an injection gun and a 16-gauge-tip transurethral needle. The vials contain 2.5 mL of silicone macroparticles (Macroplastique).

Results. The results are shown in Table 86-4. Harriss and colleagues (1996) reported on 40 patients followed for a minimum of 3 years, at which time 16 (40%) were dry and 7 (18%) were improved; in 17 (43%), treatment had failed. Twelve of the 16 required one injection and 4 needed two injections to become dry. Sheriff and coworkers (1997) reported an overall success of 48% in 34 patients after unsuccessful stress incontinence surgery, and Koelbl and colleagues (1998) reported a 60% success rate in 32 women after 12 months but noted a time-dependent decrease in success. Radley and coworkers (2001) reported a success rate of 61% (19.6% cured and 41.1% improved) in 60 women after a mean of 19 months. Barranger and coworkers (2000) in a group of 21 patients reported a dry rate of 19%, improved rate of 38%, and failure rate of 52% at a median follow-up of 31 months. It is interesting to note that they did not observe a time-dependent decrease in results. Tamanini and coworkers reported 1- and 2-year results in 21 patients with the use of a handheld noncystoscopic injector

system (see Fig. 86-4B) (Tamanini et al, 2003, 2004). There was a decrease in continence outcome after 2 years.

Zullo and coworkers followed 61 women for a minimum of 60 months and reported a cure rate of 18%, improvement rate of 39%, and failure rate of 43%. They selected patients without hypermobility (Zullo et al, 2005). Plotti and colleagues reported 84% cure and improvement rates in a series of 24 women with de novo SUI after radical hysterectomy (Plotti et al, 2009). In a randomized study in patients with SUI and urethral hypermobility, ter Meulen and colleagues compared Macroplastique, administered by the noncystoscopic injector system, with pelvic floor exercises. After 3 months, significantly more patients in the injection group were dry or improved. Eighteen of the 24 Macroplastique patients were followed for 12 months, and of these, 14 considered themselves to be cured or markedly improved (ter Meulen et al, 2009).

Ghoniem and colleagues reported results of a North American multicenter randomized trial of Macroplastique versus collagen (Ghoniem et al, 2009). After 1 year, 61.5% (75 of 122) with Macroplastique and 48% (60 of 125) with collagen had an improvement of at least 1 Stamey grade. This indicated that Macroplastique was noninferior to collagen ($P < .001$). The proportion of the patients who were dry was higher in the Macroplastique group at 36.9% versus 24.8% ($P < .05$). However, there were no significant differences in pad weight testing, quality-of-life scale, or adverse events. The same authors subsequently reported the 2-year results in the Macroplastique group (Ghoniem et al, 2010). Of those who had a benefit at 12 months, 84% maintained that level of cure or improvement to 24 months. That means that of the original 122 patients, 51.7% had a good outcome at 2 years.

Hegde and colleagues (2013) recently reported on parameters that may determine short-term success. Of 100 patients injected, 72 had a good clinical outcome and 28 were either not improved or

worsened. The groups were followed for a median of 19.3 and 17.8 weeks, respectively. The authors found that proximally located and circumferentially distributed Macroplastique was associated with the best clinical outcomes.

A systematic review and meta-analysis of Macroplastique series from 1990 to 2010 was reported by Ghoniem and Miller (2013). The authors included 24 published articles with a total of 958 patients. Short-term (<6 months) cure and improvement rates were 43% and 75%, respectively. Medium-term (6 to 18 months) rates were 37% and 73%. Long-term (>18 months) rates were 36% and 64%. The median reinjection rate was 30%, and higher reinjection rates resulted in improved long-term outcomes.

Complications. Self-limited side effects of UTI, hematuria, dysuria, urgency, frequency, voiding difficulty, and urinary retention have been reported (Ghoniem et al, 2009). Rarely erosion of the injectable occurs. The lack of a granulomatous reaction and migration of the large silicone particles may provide some benefit over smaller-particle injectable agents such as previously used Teflon. In their systematic review, Ghoniem and Miller noted a median adverse event rate of 7% for temporary urinary retention, 7% for urgency incontinence, 3% for UTI, 50% for temporary dysuria, and 45% for transient hematuria. They noted the absence of any serious reported adverse events over the 20 years of global experience (Ghoniem and Miller, 2013).

Polyacrylamide Hydrogel (Bulkamid)

PAHG is a nontoxic, nonresorbable sterile aqueous gel consisting of 2.5% cross-linked polyacrylamide and 97.5% nonpyrogenic water. It is homogeneous, stable, and nonbiodegradable and has tissue-like viscosity and elasticity. According to Lose and colleagues (2010), the acrylamide monomers are bound covalently by strong single bonds, and the linear chain structure of the polymer has been folded into a three-dimensional configuration that forms a large and very stable molecule. The total amount of residual acrylamide monomer in the PAHG is less than 1 µg/mL of the product, less than the normal daily intake of acrylamide in food and water. This means that the hazardous nature of the acrylamide monomer is not an issue.

It was originally used in plastic surgery for tissue augmentation (Breiting et al, 2004) and in the production of soft contact lenses and for intraocular applications (Lloyd et al, 2001).

As mentioned earlier, PAHG (Bulkamid) is provided in 1-mL syringes with a 12-cm 23-gauge needle and is injected via a short 0-degree urethroscope and plastic sheath (see Fig. 86-5). The kit contains two 1-mL syringes, and circumferential injection is recommended.

Results. The results are shown in Table 86-5. Lose and colleagues (2006) reported a pilot study with 25 women followed for 1 year after their last injection. Of the 21 who completed the study, 8 were dry and 9 were improved; in 4 the treatment failed. The authors noted that 11 women (44%) underwent a reinjection after 3 months because of lack of effect. In a larger European multicenter study involving 135 women, 98 of whom completed the 12-month study, Lose and coworkers (2010) reported a responder (cured or improved) rate of 66% and a dry rate of 24%; 19 patients did not respond. Using the authors' percentage of responders at 66%, the nonresponders must have comprised 34%. Therefore the results are given for a total of only 56 patients. The authors did not account for the discrepancy and it may be a pitfall in the reporting, as mentioned earlier. Efficacy was similar with either SUI or mixed incontinence. Reinjection was necessary in 35% of patients, and the responder rate was significantly lower in this group. Tooze-Hobson and colleagues (2012) reported the 2-year outcomes of the same cohort of 135 patients. Although only 86 patients were available for the 24-month follow-up, the authors used the LOCF method and presented outcomes for 124 patients at 12 months and 116 patients at 24 months. Responder rates were 67% at 12 months and 64% at 24 months. As mentioned previously, the LOCF and imputation method may overestimate the actual success rate. However, there appears to be persistence of response to 2 years. The responder rate of the group requiring reinjection was thus not significantly different from the single-treatment group.

In a 12-month study involving 29 patients (Leone Roberti Maggiore et al, 2012), 26 (89.7%) had subjective success and 23 (79.3%) had objective success. Nine patients (31%) needed reinjection 3 to 6 months after the first injection. The authors reported on sexual function using the Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire-12 (PISQ-12). Twenty-three patients

LOCF, last observation carried forward.

maintained sexual function and 6 resumed sexual function after treatment. The outcome of Bulkamid injection in women aged 80 and older was reported recently (Vecchioli-Scaldazza et al, 2014). Eighteen of 20 patients were followed for 2 years. The authors tracked pad numbers, stress testing, urodynamic parameters, quality of life assessed with the Incontinence Impact Questionnaire (IIQ-7), and patient satisfaction with the visual analog scale and Patient Global Impression of Improvement questionnaire. They noted persistence of improvement in the group parameters at 24 months but did not report the number or percentage of responders. Martan and colleagues reported the results in a complex group of 52 patients, 40 with previous unsuccessful surgery and 12 with ISD (Martan et al, 2014). All but 1 patient, who died, were followed for at least 6 months after their last treatment. The reinjection rate was 10%. After a mean of 22 months, 10 of 51 (19.6%) had a negative cough stress test result, and on subjective assessment with the International Consultation on Incontinence Questionnaire Urinary Incontinence Short Form (ICIQ-UI-SF), 8 of 51 (15.7%) reported being completely dry and 23 of 51 (45.1%) were dry or improved.

PAHG (Bulkamid) was compared with collagen in a multicenter North American randomized trial (Sokol et al, 2014). Of the 345 women, 229 received PAHG and 116 received collagen. At 1 year, 53.2% of the PAHG group and 55.4% of the collagen group showed a 50% or greater decrease in leakage and incontinence episodes. In the collagen group at 1 year, 50% reported zero SUI episodes and 70% considered themselves cured or improved, whereas in the PAHG group 47.2% reported zero SUI episodes and 77.1% considered themselves cured or improved. The results confirmed that PAHG is noninferior to collagen. The PAHG reinjection rate of 77.3% receiving two injections and 35.8% receiving three injections was higher in this study than in previous studies. The mean total volume of 3.3 mL in this study was more than twice the mean total volume of 1.53 mL in the European multicenter PAHG study, which reported a 1-year responder rate of 67% (Tooze-Hobson et al, 2012). The required volume of agent and the numbers of procedures determine cost. The commercial kit contains a total of 2 mL of PAHG, so two or more kits and procedures may be required to achieve a 77% responder rate.

Complications. In the large multicenter RCT, 381 adverse events were seen in 136 women, 59.4% of the total number treated with PAHG (Sokol et al, 2014). The most common procedure- or injectable-related complications were UTI (12.3%), transient pain at implant site (48.1%), and urinary retention after the procedure (17.3%). Other complications were hematuria (3.7%), nocturia (3.7%), de novo urgency (2.5%), and urgency urinary incontinence (2.5%). Rare problems are vaginal discomfort and worsening incontinence. No serious complications have been reported.

Calcium Hydroxylapatite (Coaptite)

CaHA, which is a normal constituent of bone, can be manufactured into particles of a spheric mean diameter of 100 μ m (75 to 125 μ m) suspended in a carboxymethylcellulose gel carrier. Exogenous CaHA has been used in orthopedic and dental applications (Bucholz, 2002), as well as soft-tissue augmentation of vocal cords (Belafsky and Postma, 2004), face (Tzikas, 2004), and the ureteral orifice for reflux (Mevorach et al, 2006). Animal experiments have demonstrated safety and biocompatibility. It stimulates fibroblast infiltration when placed into soft tissue, which may explain its long-term bulking effect after degradation of the carrier gel (Mayer et al, 2007).

The implant is currently supplied in 1-mL syringes and can be injected via a transurethral approach through a 21-gauge needle.

Results. Mayer and colleagues (2001) reported initial results in 10 women with ISD and limited hypermobility. After 1 year, 7 reported substantial improvement, 2 improved, and 1 had no change. No significant complications were reported. In a randomized prospective trial of CaHA versus collagen, Mayer and coworkers (2007) reported results in 231 women. Up to five injections were performed in the first 6 months of the trial. At 12 months, 83 (63.4%) of 131 CaHA patients showed improvement of one Stamey grade or more

versus 57 (57%) of 100 collagen patients ($P = .34$). There was no difference in cure (39% CaHA vs. 37% collagen) or improvement (50% CaHA vs. 46% collagen) rates. More CaHA patients required only one injection, and the total average injected volume was lower (4.0 mL vs. 6.6 mL respectively; $P < .0001$).

Complications. Minor adverse events such as transient retention (41%), UTI, and urgency incontinence (5.7%) were reported (Mayer et al, 2007). Serious adverse events were vaginal wall erosion of the implant and dissection of the material beneath the trigone. Because the injectable has a greater particle density than collagen, it is thought to have the potential to cause more local tissue pressure effects. Rare complications are urethral mucosal prolapse (Palma et al, 2006; Lai et al, 2008) and injection site granulomas (Gafni-Kane and Sand, 2011).

Porcine Dermal Collagen

Porcine dermal collagen implants have been used in hernia repairs and pelvic floor reconstruction (Harper, 2001; Dench et al, 2006). It is maintained in its original three-dimensional forms and is close to human dermis in architecture (Meyer et al, 1978). It is biocompatible, and patients do not have to be skin tested as with bovine collagen.

Bano and colleagues (2005) reported early results of a randomized trial of porcine dermal collagen versus Macroplastique. There were 25 patients in each arm. The porcine collagen was injected periurethraly in 21 patients. At 6 months, 15 (60%) of 25 in the collagen group were dry, and 10 were unchanged or worse (40%). In the Macroplastique group, 9 (36%) were dry, 1 (4%) improved, and 14 (56%) were unchanged or worse. There were no significant differences between the groups. Minor complications of transient retention and urgency incontinence were seen in both groups and were similar.

Autologous Chondrocytes

A bulking agent composed of autologous chondrocytes has been used to treat children with vesicoureteral reflux (Diamond and Caldamone, 1999). Animal studies of the implant demonstrated stability and lack of migration over time (Atala et al, 1994; Cozzolino et al, 1999). The injectable material consists of autologous chondrocytes in a calcium alginate gel administered endoscopically through a 22-gauge needle. The chondrocytes obtained from biopsy of the external pinna of the patient's ear are expanded in tissue culture and combined with a carrier gel that degrades after injection.

Bent and coworkers (2001b) reported 12-month results in 32 women after a single outpatient injection in a multicenter trial. Incontinence grading indicated 16 patients dry and 10 improved for a total of 26 (81.3%). Side effects were minimal.

Adjustable Continence Therapy

The Adjustable Continence Therapy (ACT) device was developed as an alternative to bulking agents that would not migrate (Kocjancic et al, 2008). It consists of two inflatable silicone balloons attached to silicone tubing with a titanium and silicone port (Fig. 86-7). The procedure can be done using local, regional, or general anesthesia. The balloons are placed into the periurethral space at the bladder neck with introducer devices inserted through two 1-cm incisions in the labial sulci at the level of the vaginal introitus. The procedure is carried out under fluoroscopic guidance with a contrast-filled Foley balloon positioned at the bladder neck. After the correct position is ascertained, the device balloons are inflated with 1 to 1.5 mL of an isotonic solution (sterile water and contrast material). The aim is to increase urethral resistance and support the bladder neck with the inflated balloons (Stecco et al, 2006). The ports are buried in the subcutaneous tissue of the labia to enable postoperative reinjection of the balloons if necessary (Kocjancic et al, 2008). Beginning at 6 weeks, additional fluid, usually with volumes of 2 mL, can be added to the balloons by percutaneous injection

Figure 86-7. Illustration of Adjustable Continence Therapy balloon device for women. **A**, Schematic diagram showing percutaneous placement of the balloons on both sides of the bladder neck. **B**, Fluoroscopic picture showing contrast agent in the bladder, Foley catheter, and balloons. (From Aboseif SR, Franke EI, Nash SD, et al. The Adjustable Continence Therapy system for recurrent female stress urinary incontinence: 1-year results of the North America Clinical Study Group. *J Urol* 2009;181[5]:2187–91.)

through the port sites, if necessary. Each balloon has a volume of 8 mL.

Results. Chartier-Kastler and colleagues (2007) reported on a series of 68 women. Of the 29 women followed for a mean of 2 years, 87% were dry or improved. However, 26 patients underwent explantation, and 13 records were incomplete or were missing data. Kocjancic and colleagues (2008) performed implantation in 49 patients, of whom 38 were followed for more than 1 year. Of these, 26 of 38 (68%) were dry, 6 of 38 (16%) improved, and in 6 of 38 (16%) the procedure failed. In 62%, one to five fluid additions were necessary throughout the follow-up period. Wachter and coworkers (2008) reported a series of 41 women. The dry rate was 44%, marked improvement was seen in 15%, and 41% had slight improvement or no change. Device adjustment was needed in 70% of patients. Aboseif and coworkers (2009) reported a North American study consisting of 162 patients, of whom 84% had undergone at least one unsuccessful surgical procedure for SUI. Of those followed for 1 year or longer, 107 of 140 (76.4%) improved by 1 or more Stamey grades, 67 of 130 (52%) had less than 2 g on pad weight testing, and 102 of 126 (81%) had a greater than 50% reduction in provocative pad weight. Within 9 months of implantation, a mean of 2.3 balloon readjustments were required.

In a subsequent series, Kocjancic and colleagues (2010), reported 6-year outcomes on 29 of 57 patients. On the Patient Global Impression of Improvement questionnaire, 64% of patients rated their symptoms as very much improved, 23% as much improved, and 13% as minimally improved or unchanged. In a second report from the North American multicenter study, Aboseif and coworkers (2011) reported on 1-year outcomes in 77 of 89 patients. With an intention-to-treat analysis, 39.3% were dry (<2 g on provocative pad weight test) or 77.5% improved (≥50% reduction on pad weight test).

Because volume adjustments were done during the follow-up periods in all series, there are no data available on continence outcome long after cessation of fluid addition.

Complications. Complications have occurred in 24% (Aboseif et al, 2009) to 39% (Wachter et al, 2008) of patients, with most classified as mild to moderate. Intraoperative urethral or bladder perforation has been reported in 3% to 17% of patients. Recent intraoperative perforation rates are 3.7% to 45% (Phe et al, 2014). During the first year postoperatively, complications reported are balloon migration (6.5% to 17.5%) or dysfunction (0.6% to 8.9%). Others include urethral erosion (2% to 15%), cutaneous

erosion of the port (3% to 75%), device infection (0.6% to 6%), treatment failure or worsening of incontinence (2.5% to 11.7%), dysuria or retention (1.5% to 6.8%), and de novo urgency (10.5%) (Phe et al, 2014).

The explantation rate is 15% to 30.8%. The reimplantation rate is up to 50% in various studies (Phe et al, 2014).

Overall, the procedure may be more suited to patients after surgical failures. To date, 38% to 100% of patients in reported series have had previous unsuccessful SUI surgery (Phe et al, 2014). Long-term durability still has to be established.

Cell-Based Therapy

Cell-based therapy for SUI aims at repairing deficient anatomic components of the urethral continence mechanism. Because there is still debate about the mechanism for SUI, it is not specifically known which components—the urethral mucosa, anatomic supports, smooth or striated muscle—play a distinct role in the patient (Delancey, 2010). However, cell-based therapies have demonstrated experimentally an increase in most or all of the components of the sphincter mechanism.

Cells Used in Cell-based Therapies for Stress Urinary Incontinence. Embryonic stem cells (ESCs), derived from the inner cell mass of the blastocyst, possess a vast proliferation potential and can transform into any cell type in the body (Gras and Lose, 2011). Because of the potential risk of tumor formation and immunologic and ethical concerns, potential use of these cells is limited. In contrast to ESCs, adult stem cells (ASCs), or tissue-specific stem cells, are involved in normal growth, cell turnover, and maintenance and repair processes (Gras and Lose, 2011). Their limitations of mortality and limited differentiation potential also may make them safer (Staack and Rodriguez, 2011). Mesenchymal-derived stem cells (MSCs) (connective tissue from the embryonic mesoderm) have been investigated for use in SUI. Examples of MSCs are those isolated from bone marrow (bone marrow stem cells [BMSCs]) or adipose tissue (adipose-derived stem cells [ADSCs]) and hematopoietic stem cells from blood or umbilical cord (umbilical cord blood stem cells [UCBSCs]). The cells can be expanded before transplantation in a culture medium and can release paracrine factors to stimulate surrounding tissue regeneration. Large numbers of progenitor cells with a specialized phenotype can be obtained by in vitro growth. Examples of these are chondrocytes

from cartilage and skeletal muscle–derived stem cells (MDSCs) that can form myoblasts (Staack and Rodriguez, 2011). Autologous cells are preferred (Gras and Lose, 2011).

Animal Studies. Although BMSCs have been used widely in other sites, their use in the lower urinary tract is limited to experimental studies owing to difficulties in harvesting the cells (Aref-Adib et al, 2013). A relatively large number of animal studies have demonstrated that injection of cells isolated from skeletal muscle (MDSCs) can repair urethral injury or denervation. The cells survive and a normal repair process occurs with formation of new innervated myofibers, smooth muscle cells, loose interstitial tissue, and vessels. These observations have been confirmed by histologic and immunohistochemical tests. Functional testing on isolated urethral tissue and urodynamic tests on whole animals also have supported the results (Gras and Lose, 2011). ADSCs can differentiate into fibroblasts, myoblasts, smooth muscle cells, endothelial cells, or skeletal muscle and promote nerve regeneration (Staack and Rodriguez, 2011). Experimental studies have demonstrated immunohistochemical evidence of repair and improved urethral function in incontinent rat models. Furthermore, the abundance of donor tissue and easy isolation may allow for use of freshly isolated rather than cultured cells (Roche et al, 2010). Although animal studies are promising, most are small with short follow-up. They involve young animals that may not reflect an older human population (Aref-Adib et al, 2013).

Human Studies. The first study involved injecting autologous ear chondrocytes as a urethral bulking agent in 32 women (Bent et al, 2001b). After 1 year, 81% were improved and 50% were dry. No long-term follow-up has been published.

Mitterberger and coworkers (2007) reported on 123 women with SUI who underwent transurethral ultrasound-guided injection of autologous fibroblast injection into the urethral submucosal and myoblast injection into the rhabdosphincter. The cells were cultured from skeletal muscle biceps biopsies. One year after therapy, 94 women (76%) were cured, 16 (13%) were substantially improved, 9 (7%) were slightly improved, and 4 were lost to follow-up. No complications were reported. However, Strasser and coworkers, from the same group in Innsbruck, Austria (Strasser et al, 2007), published results of a randomized trial of autologous myoblast versus collagen injection, and the article was subsequently retracted by *The Lancet* owing to irregularities in the conducting of the clinical trial (Kleinert and Horton, 2008). This retraction has left us with relatively small, short-term, or early-phase studies in the literature to date.

The outcome of injection of autologous MDSCs via a transurethral ultrasound device followed by 5 weeks of self-administered transvaginal functional electrical stimulation was reported in 39 women (Blaganje and Lukanovic, 2013). At 6 months, 23.7% of the patients considered their SUI cured, and 52.6% reported improvement. Cornu and coworkers (2014) reported the long-term outcome of use of autologous MDSCs in 12 women, 11 of whom had undergone multiple previous SUI procedures. Of the 2 patients who were dry at 1 year, both were still dry at 6 years. Of the 5 who were considered improved at 1 year, all worsened, but 3 remained satisfied. There were 5 failures.

Stangel-Wojcikiewicz and coworkers (2014) reported 2-year outcomes of transurethral sphincter injections of autologous MDSCs harvested from the deltoid in 16 women with SUI. After 2 years, 8 were dry and 4 were improved; in 4 the treatment failed. The authors noted that the mean time for initial improvement was 4.7 months, and improvement continued for 8 months. They also noted that success was seen with a relatively small number of cells. Peters and colleagues (2014) reported the safety and 12-month efficacy outcomes of two pooled phase II studies of autologous MDSC injections in 72 of the 80 study patients. The investigators used four increasing doses of intrasphincteric injections (10^4 , 50×10^4 , 100×10^4 , and 200×10^4) of MDSCs obtained by quadriceps biopsy. They found that higher-dose groups tended to have greater percentages of patients with at least a 50% reduction in stress leaks and pad weight. All groups had statistically significant improvements in Urogenital Distress Inventory (UDI-6) and IIQ-7 scores.

Lee and coworkers (2010) reported the outcome of transurethral injection of a 2-mL suspension of umbilical cord blood stem cells in 36 of 39 women. After 12 months, 26 (72.2%) were cured or 50% or more improved, and in 10 (27.8%) the procedure failed.

To avoid the need for expensive cell preparation technology, Gras and colleagues tested the effect of transurethral injection of minced autologous striated muscle harvested and prepared for use at the time of urethral injection (Gras et al, 2014). Periurethral injections were done with urethral visualization with a vaginal ultrasound probe in 20 women with uncomplicated and 15 with complicated SUI. After 12 months, cure and improvement were noted in 25% and 63% of the uncomplicated group and 7% and 57% of the complicated group, respectively. The results appear similar to reports with harvested stem cells.

Most adverse events have been minor and easily managed. Peters and colleagues (2014) reported that biopsy-related adverse events occurred in 4 patients and included wound hematoma (2), procedural dizziness and associated responses (2), postoperative bleeding requiring sutures (1), and joint swelling (1). Injection procedure-related adverse events occurred in 18% (14 of 80), and included dysuria (7), pelvic or abdominal pain (4), vulvovaginal pruritus (3), urinary urgency (2), and transient hematuria (2).

The technology looks promising and may provide advantages over bulking agents. However, there are no large or comparative studies, and no long-term data are available yet. Furthermore, the ultimate cost of the technology will determine whether it becomes a feasible alternative.

Autologous Fat

Autologous fat has been used for esthetic and defect reconstruction since the 1980s (Billings and May, 1989). Although fat is biocompatible and readily available, 50% to 90% of the transferred adipose tissue graft may not survive (Horl et al, 1991). Graft survival depends on minimal handling, low suction pressure during liposuction, and the use of large-bore needles. Smaller grafts survive better than larger ones (Bircoll and Novack, 1987).

The procedure involves harvesting abdominal wall fat by liposuction with use of either local (Trockman and Leach, 1995) or general anesthesia (Su et al, 1998). The injection is usually carried out via the periurethral route with a 16- or 18-gauge needle. Post-procedure care may involve intermittent catheterization or even a suprapubic tube (Su et al, 1998).

Results. A number of reports of urethral fat injections have been published and appear in Table 86-6. Most of the series report short-term results, with success apparently lower than that with other injectables, apart from the study of Su and colleagues (1998) with a follow-up of more than 12 months. Palma and coworkers (1997) showed that repeat injections improved the cure rate from 31% to 64%. Haab and colleagues (1997) reported a comparative study with collagen. After a mean of 7 months, 13% of the women with fat injection were cured versus 24% of the women with collagen injections. The subjective improvement rate was also higher with the collagen. Lee and colleagues reported a randomized double-blind study of autologous fat versus saline injection (Lee et al, 2001). At 3 months, 6 of 27 (22.2%) and 6 of 29 (20.7%) women were cured or improved in the fat and saline groups, respectively. In this study, periurethral fat injection did not appear to be more efficacious than placebo in treating stress urinary incontinence.

Since the publication of the randomized trial of Lee and colleagues (2001) showing that fat was no more efficacious than saline, no further publications have appeared in the literature. Furthermore, the report of a death from fat embolism (Currie et al, 1997) most likely discouraged additional studies. However, experimental work on the use of ADSCs to help improve function after urethral injury has progressed in the rat model (Lin et al, 2010) and in a pilot study with five women with SUI (Kuismanen et al, 2014).

Complications. Reported complications are similar to those of other injectables and include UTI, retention, hematuria, and extravasation. Additional problems with the donor site, the abdominal wall, such as pain, hematomas, and infection, may also be seen.

TABLE 86-6 Results of Autologous Fat Injection

STUDY	NO. OF PATIENTS	FOLLOW-UP (mo)	NO. OF PATIENTS WHO BECAME DRY (%)	NO. OF PATIENTS WHOSE CONDITION IMPROVED (%)	NO. OF PATIENTS IN WHOM TREATMENT FAILED (%)
Cervigni et al (1994)	11	22.6	6 (54.5)	2 (18)	3 (27.3)
Santarosa and Blaivas (1994)	12	11		7 (58)	5 (42)
Trockman and Leach (1995)	32	6	4 (13)	14 (44)	14 (44)
Haab et al (1997)	45	7	6 (13)	13 (29)	26 (58)
Palma et al (1997)	30	12	1 injection: 4/13 (31) 2 injections: 11/17 (65)	—	—
Su et al (1998)	26	Mean 17.4 (range 12-30)	13 (50)	4 (15)	9 (35)

Other noteworthy complications are urethral pseudolipoma (Palma et al, 1996) and fat embolism (Sweat and Lightner, 1999), one of which was fatal (Currie et al, 1997).

Dextranomer Hyaluronic Acid Copolymer (Deflux, Zuidex)

Dextranomer hyaluronic acid (DHA) copolymer consists of dextranomer microspheres (80 to 250 μ m) in a carrier gel of non-animal-stabilized HA. The gel is a biocompatible, biodegradable material free of animal products, has no immunogenic properties, and has been shown not to migrate to different organs after submucosal injection (Stenberg et al, 1999). Stenberg and colleagues first reported the use of this substance in 20 women. They injected it transurethraally through a cystoscope. After 6 months, 9 patients were cured and 7 improved; in 3, the treatment failed. Six to 7 years later, 5 remained dry and 4 were still improved. Overall, 9 of the original 20 had a long-term response.

Subsequently the procedure was modified by injection of the DHA copolymer through a system consisting of a handle (Implacer) through which four needles with attached syringes are mounted. A plastic protector is pushed forward to sheathe the needles. The device is inserted into the urethra and positioned below the bladder neck by measurement of the distance from the meatus. The barrel is slid backward to unsheath the four needles, and a total of 2.8 mL of DHA is injected blindly into the urethra, 0.7 mL into each quadrant. Van Kerrebroeck and colleagues (2004) reported early results in 42 women. Thirty-two (76%) had improvement in leakage at 3 and 12 months. Chapple and colleagues (2005) reported the results of 142 patients treated in a European multicenter trial. The protocol consisted of an initial injection followed by another at 8 weeks if required. A total of 61 patients (43%) underwent the second injection. At month 12, 77% of the patients demonstrated a positive response—a 50% or greater decrease in leakage on provocative testing.

Lightner and colleagues (2009) reported 12-month outcomes of a North American prospective 2:1 randomized trial of Zuidex-Implacer versus collagen injected cystoscopically in 344 women. The study failed to demonstrate that Zuidex was noninferior to collagen. A 50% reduction in urinary leakage on provocation testing, the primary outcome, was achieved in 84% of collagen-treated women versus 65% of Zuidex-treated women. There was also a 15% incidence of pseudoabscess formation. This negative trial prompted the company to withdraw the Zuidex product.

To determine whether the relatively poor success and high rate of pseudoabscess formation was related to the material or the Implacer, Lightner and coworkers (2010) did a study with cystoscopically guided injections of DHA copolymer. Of the 35 treated women with ISD, 23 returned their post-treatment questionnaires.

At an average of 16 months after the last injection, 47% were cured or markedly improved; however, 6 of 13 without pretreatment urgency also developed de novo urgency incontinence. Pseudoabscesses developed in 4 patients (11%). The authors concluded that the injectable itself is associated with the poor outcomes and further study is not warranted. A similar product, Deflux, approved for vesicoureteral reflux, is still available and can be used without the Implacer.

Complications. The reported side effects were similar to those of other injectables, apart from injection site infections and pseudocyst or pseudoabscess formation requiring drainage or excision (Chapple et al, 2005; Petrou et al, 2006; Abdelwahab and Ghoniem, 2007; Lightner et al, 2010). Urethrovaginal fistula after sterile abscess has also been reported (Hilton, 2009).

KEY POINTS: OUTCOMES OF INJECTABLE AGENTS FOR FEMALE STRESS URINARY INCONTINENCE

- Until it was discontinued in 2010, collagen was the most widely used and reported injectable agent.
- Results of injectables may be optimized if there is circumferential distribution of the injection material in the proximal urethra.
- In two separate randomized clinical trials versus collagen, both carbon-coated zirconium beads (Durasphere) and CaHA (Coaptite) showed similar results to collagen after a 1-year follow-up.
- In a randomized clinical trial comparing silicone microparticles (Macroplastique) with collagen, silicone microparticles were shown to be noninferior to collagen after 1-year follow-up.
- PAHG (Bulkamid) was also shown to be noninferior to collagen in a North American 1-year multicenter randomized trial.
- Complications of currently used injectables are usually mild and may be self-limited. Common ones include transient retention, urinary infection, de novo urgency and urgency incontinence, and hematuria.
- ACT silicone balloons were devised as a nonmigrating injectable alternative. No comparative studies have been done, and long-term durability has not been demonstrated.
- Cell-based therapies are in the investigational stages. Clinical reports are few and have included autologous ear chondrocytes, MDSCs and UCBSs.

PATHOPHYSIOLOGY OF POSTPROSTATECTOMY INCONTINENCE AND THE USE OF INJECTABLE AGENTS FOR MALE STRESS URINARY INCONTINENCE

Postprostatectomy incontinence (PPI) may be caused by bladder dysfunction, sphincter dysfunction, or a combination of the two. Urodynamic investigations can be helpful to rule out bladder outlet obstruction or significant bladder dysfunction. In addition to incontinence symptoms, storage and voiding symptoms may be associated (Gray et al, 1999; Hollenbeck et al, 2002). Urodynamic studies have demonstrated that sphincter incompetence occurs as the sole cause in more than two thirds of patients, whereas isolated bladder dysfunction (detrusor overactivity, poor compliance, detrusor underactivity during voiding) is uncommon, occurring in less than 10% of patients (Ficazzola and Nitti, 1998; Groutz et al, 2000b). However, sphincter and bladder dysfunction can coexist in at least one third of incontinent patients. Decreased sphincter resistance may be caused by tissue scarring in some cases and is reflected by a low urethral compliance; however, this parameter is difficult to measure (Groutz et al, 2000b). Scarring may lead to an anastomotic stricture evidenced by endoscopy or urethrography and may be clinically suspected when both incontinence and decreased force of stream coexist.

The preoperative length of the membranous urethra determined on magnetic resonance imaging (MRI) has been shown to be related to time to postoperative continence (Coakley et al, 2002). Urodynamic studies have revealed that a reduced functional urethral length was predictive of incontinence (Hammerer and Huland, 1997; Van Kampen et al, 1998; Wei et al, 2000). Cameron and coworkers (2015) showed in a pilot study that patients with PPI were less able to increase urethral pressure during a Kegel maneuver and had shorter anatomic urethral sphincter length on MRI than continent controls. The state of a patient's pelvic floor may also influence continence or return to continence after radical prostatectomy. Physiotherapy and pelvic floor rehabilitation have been shown to improve or enhance continence (decreased time to final continence level) in the postoperative period in two randomized studies, but only if such measures are instituted before or immediately after catheter removal (Van Kampen et al, 2000; Parekh et al, 2003). Maximum difference between physiotherapy and no treatment is achieved at 3 months, with almost no difference at 12 months. A randomized study in which randomization occurred 6 weeks after surgery showed no difference in continence at 6 months (Wille et al, 2003).

Urethral bulking theoretically works by adding bulk and increasing coaptation at the level of the bladder neck and proximal urethra. Several agents have been used including bovine collagen (Contigen) and silicone microparticles (Macroplastique). All agents share similar problems including the need for multiple injections, deterioration of effect over time, and low cure rates. An alternative technology with implanted adjustable volume balloons (ProACT) will be discussed.

Workup

Basic evaluation includes history, physical examination, urinalysis, and PVR urine. A frequency-volume chart (Griffiths et al, 1993) or bladder diary is also helpful. A pad test quantifies the severity of incontinence. The 24-hour home test is the most accurate pad test for quantification and diagnosis and the most reproducible (Mouritsen et al, 1989). The 1-hour pad test is widely used because it is more easily done and standardized. PVR urine is a good estimation of voiding efficiency (Diokno et al, 1988; Starer and Libow, 1988).

Blood testing (blood urea nitrogen [BUN], creatinine, glucose) is recommended if compromised renal function is suspected or documented (Fantl et al, 1996).

Uroflowmetry may be helpful to assess voiding function.

Cystourethroscopy is done to verify integrity of the urethral wall and bladder neck and the status of the bladder (e.g., trabeculation, stones, diverticula). Injectables are not effective with

scarred supramembranous urethras because the tissues cannot expand with the agent. The status of the urethra should be assessed preoperatively.

Invasive urodynamic studies may be useful to assess bladder and urethral function before interventional therapy (Herschorn et al, 2013). Detrusor overactivity or decreased bladder compliance demonstrated on multichannel testing may be contributing to symptoms and may merit alternative treatment. Sphincter weakness can be documented by Valsalva maneuver (McGuire et al, 1993) or cough (Schick, 1985) ALPP, but its reproducibility has been studied in women and not men. Although ALPP may be helpful, it has been shown to be a poor predictor of incontinence severity after radical prostatectomy (Twiss et al, 2005). Furthermore, in male patients, ALPP measurement may be better accomplished via a rectal catheter because a urethral catheter may occlude a scarred urethra (Flood et al, 1996). The evidence supporting the use of various urodynamic tests in the diagnosis of PPI was recently reported in a consensus publication from the International Consultation on Incontinence–Research Society (ICI-RS) (Rosier et al, 2014). Flow, PVR volume, cystometry, and pressure-flow study results have level 4 evidence, and urethral pressure profile, video-urodynamics, surface electromyography (EMG), and ambulatory urodynamic studies have no evidence. Furthermore, evidence supporting the predictive value of urodynamic studies is also lacking. Invasive urodynamic studies are therefore an optional test.

Injection Techniques

Retrograde Injection

Male patients are placed in the lithotomy position, and the surgical field is prepared in the usual sterile fashion (Fig. 86-8A). The procedure can be performed using local, regional, or general anesthesia. If local anesthesia is used, 2% topical urethral lidocaine jelly can be inserted 10 minutes before instrumentation. In some patients, preoperative sedation may also be of benefit. A 20- or 22-Fr cystoscopic sheath is used with a 0-degree or 30-degree lens. GAX collagen is provided in a 3.0-mL Luer-Lok syringe containing 2.5 mL of injectable material. The syringe attaches to a 5-Fr injection catheter containing a 1.5-cm 20-gauge needle at the tip. Most men are injected transurethally under cystoscopic vision.

The postprostatectomy urethra is frequently scarred and not very pliable; thus, several needle insertions are frequently needed to deposit sufficient material to produce urethral coaptation. The injection is completed in up to four quadrants after localization of the appropriate level in the proximal urethra. The needle is advanced under the urethral mucosa with the beveled portion of the needle facing the urethral lumen to allow for layering of the material. The injectable material is then delivered, creating a bleb under the urethral mucosa that protrudes into the urethral lumen. This is performed in a circumferential manner in four quadrants, creating a bleb in each quadrant. After completion, the urethral mucosa should be completely coapted, creating the appearance of an obstructed urethra. Extrusion of the injectable agent into the urethral lumen as the needle is withdrawn may occur. This may be prevented in most cases by leaving the needle in place for at least 30 seconds after the injection is completed or by flushing the material with saline. The loss of additional material is diminished by preventing advancement of the cystoscope proximal to the injection sites. If material extravasation occurs in all quadrants during injection, the procedure should be terminated and rescheduled (Appell and Winters, 2007).

Antegrade Injection

Because of less-than-optimal results, an alternative method of injecting collagen in men was introduced, involving a suprapubic antegrade approach. The antegrade approach has the advantage of direct visualization of the bladder neck and the injection of material into more supple, less scarred urethra (see Fig. 86-8B). The patient is placed in the lithotomy position and flexible cystoscopy is carried

All rights reserved.)

out, simultaneously filling the bladder. A percutaneous suprapubic puncture allows placement of two guidewires into the bladder. The site is dilated to 16 Fr with Amplatz dilators. A sheath may be used, but commonly the cystoscope (flexible or rigid pediatric) can be advanced over one of the guidewires into the bladder. A small red rubber catheter or the flexible cystoscope can be used to assist in localization of the bladder neck. The needle is placed just under the urethral mucosa at the level of the bladder neck and advanced proximally, meaning it is pulled back toward the bladder. The bladder neck closes off completely as the material is injected. Injection stops after the bladder neck closes off, with the two sides meeting in

apposition near the midline. A small suprapubic tube can be placed to avoid the possible necessity of urethral catheterization.

Periprocedure Care

Prophylactic antibiotics with a fluoroquinolone or TMP-SMX for 24 hours or less can be recommended (Wolf et al, 2008). An additional 2 to 3 days has also been suggested (Appell and Winters, 2007).

The patient then voids and can be discharged. Urinary retention can be treated by insertion of a fine Foley catheter (12 to 14 Fr or smaller) overnight or intermittent catheterization. Although not specifically reported, an indwelling Foley catheter may cause molding of the agent and lead to early failure, so long-term catheterization should be avoided.

Reinjections

The same schedule applies as in female patients.

Glutaraldehyde Cross-linked Bovine Collagen (Contigen)

As mentioned earlier, GAX collagen was discontinued in 2010. Its use is presented here because there is still more experience with this injectable than with all others to date.

GAX collagen was injected transurethral with cystoscopic monitoring into the supramembranous urethra. It has also been injected percutaneously through a suprapubic approach in an antegrade manner. The published results for both techniques are shown in Tables 86-7 and 86-8.

For collagen, success rates for PPI range from 36% to 69%, with 4% to 20% of patients reporting being dry (McGuire and Appell, 1994; Aboseif et al, 1996; Cummings et al, 1996; Sanchez-Ortiz et al, 1997; Smith et al, 1998a; Cespedes et al, 1999; Klutke et al, 1999; Tiguert et al, 1999). Unfortunately, the end points in most of these studies are subjectively based, making comparisons difficult; however, it is clear that cure rates (total dryness) are low, and multiple injections are required to achieve modest rates of subjective improvement. There is no advantage of delivery technique (retrograde vs. antegrade). Several authors have identified factors that negatively affect results, including extensive scarring or stricture formation, previous radiation, and high-grade stress incontinence and low ALPP (Aboseif et al, 1996; Sanchez-Ortiz et al, 1997; Smith et al, 1998a; Cespedes et al, 1999). One study reported more favorable results for collagen in treating incontinence after transurethral prostatectomy as opposed to radical prostatectomy (35.2% social continence vs. 62.5%) (Smith et al, 1998a). Westney and coworkers (2005) reported long-term results in 322 men followed for a mean of 40.1 months. Overall, 55 patients (17%) were dry for a mean of 11.1 months and required 3.8 injections with a total volume of 29.3 mL. Their mean duration of response was 11.1 months. In those who experienced any improvement, the mean duration of response was 6.3 months. These authors concluded that collagen was of some benefit but the duration of response was limited.

Collagen injection does not adversely affect outcomes of artificial sphincter implantation and does not increase the complication rate (Gomes et al, 2000), nor does collagen injection adversely affect the outcome of the bone-anchored male sling (Comiter, 2002; Onur and Singla, 2006). The cost-efficacy of injections remains to be determined.

Complications. In addition to the complications reported in the section on female patients, worsening of incontinence symptoms may occur in 1.5% of male patients (Westney et al, 2005).

Currently Used Injectable Agents

Silicone Microimplants (Macroplastique)

Colombo and colleagues (1997) reported on 6 men with PPI followed for a mean of 15.5 months. Of 6 patients, 5 became dry and 1 was substantially improved. Although initial success has been

demonstrated with silicone microimplants, results deteriorate over time. Bugel and coworkers treated 15 patients. They noted rapid deterioration after initial improvements with success rates of 40%, 71%, 33%, and 26% at 1, 3, 6, and 12 months, respectively (Bugel et al, 1999). They also noted that a urethral closure pressure of at least 30 cm H₂O was essential for success. Kymala and colleagues (2003) studied 50 patients with mild-to-moderate SUI (average 48 mL on 1-hour pad test); 12% achieved short-term continence after one injection, and an additional 20%, 18%, and 10% achieved continence with 2, 3, or 4 injections, respectively. Follow-up, however, was limited to 3 months. In a series of 14 men with spinal injuries and SUI, Hamid and coworkers (2003) reported that 5 (36%) were dry, 3 (21%) were improved, and in 6 (43%) the procedure had failed after a mean follow-up of 35 months. Longer-term deterioration of outcome was also reported by Lee and coworkers (2014). In a group of 30 incontinent men, the cure and improvement rate at 1 month was 43% (13 of 30), but at 6 months only 6 of 19 evaluable patients had a successful result (1 dry, 5 improved).

In a randomized trial of the Artificial Urinary Sphincter (AUS) versus Macroplastique injection in patients with minimal SUI (the vast majority had SUI after benign prostatic hyperplasia [BPH] surgery, with more than one third of the cohort having SUI after open radical prostatectomy), Imamoglu and colleagues (2005) demonstrated no difference in success with AUS versus Macroplastique in men with mild incontinence. However, in patients with

more severe incontinence, the AUS was superior, with minimal improvement seen after transurethral Macroplastique.

Complications. Side effects in men are similar to those reported in women.

Adjustable Balloons (ProACT)

The adjustable balloon procedure is based on the concept of passive compression and uses balloons located on either side of the urethra. Balloons may be progressively inflated until there is optimal coaptation, thereby achieving continence. The biomaterial ACT was originally developed for female SUI and subsequently was applied to male incontinence. The male ProACT device was first reported in 2000 (Hubner, 2000).

The device consists of a silicone elastomer balloon attached to an injectable titanium port with a silicone tube (Fig. 86-9). A balloon is implanted on either side of the urethra, either under the bladder neck for post-radical prostatectomy incontinence, or under the verumontanum for post-transurethral resection of the prostate (TURP) incontinence. The ports are positioned subcutaneously in the scrotum, allowing simple access for percutaneous adjustment of the balloon volume. The implantation is performed with the patient under general or spinal anesthesia through a short perineal incision. A trocar covered with a U-shaped sheath is inserted up to the site of implantation, and then the balloon is pushed along

Figure 86-9. Illustration of Adjustable Continence Therapy balloon device for men. A, Balloon, trocar, and U-shaped insertion device are shown. Syringe with contrast agent is connected to balloon port. B, Fluoroscopic picture showing contrast agent in the bladder and urethra with balloons near the bladder neck. (From Trigo-Rocha F, Gomes CM, Pompeo AC, et al. Prospective study evaluating efficacy and safety of Adjustable Continence Therapy [ProACT] for post radical prostatectomy urinary incontinence. *Urology* 2006;67[5]: 965–69.)

inside the sheath. Fluoroscopic and urethroscopic guidance are used for the procedure. Transrectal ultrasound-guided implantation (Gregori et al, 2006, 2010) is a possible option. The balloons are filled with 2 mL of isotonic sterile water and contrast medium during the initial procedure. After approximately 1 month, the balloons are refilled with 1 mL of this solution at each period (maximum filling is 8 mL) until continence is achieved. The adjustments of the filling are volume limited and are carried out step by step to obtain a pseudocapsule surrounding the balloons to minimize the risk of urethral erosion or migration.

Results from 11 studies are shown in Table 86-9. The duration of follow-up was variable, and not all patients undergoing implantation had their follow-up documented. The percentage of successfully treated patients was frequently based on the number of patients still in the study at the follow-up point in time and not on the total number entering the study. This raises the success rates because the failures, or patients lost to follow-up, were dropped from the denominator. The reported pad-free rate varied from 14% (Cansino Alcaide et al, 2007) to 67% (Kocjancic et al, 2007). The percentage of patients using 0 or 1 pad per day ranged from 44% (Kjaer et al, 2012) to 81% (Gilling et al, 2008). The mean procedure time ranged from 19 minutes (Kocjancic et al, 2007) to 53 minutes (Roupret et al, 2011). Along with improvements in pad use, there were parallel improvements in Incontinence Quality-of-Life instrument (I-QOL) score (Hubner and Schlarp, 2005; Trigo-Rocha et al, 2006; Lebret et al, 2008). The mean number of postoperative

adjustments of the balloon was 3 to 5, with some patients requiring up to 15.

In a simultaneously treated cohort study from two centers, Crivellaro and colleagues (2008) reported no difference in outcome for the adjustable balloons versus bone-anchored male sling. At a mean follow-up of 19 months, 30 of 44 men (68%) who had undergone adjustable balloon procedures were dry and 7 (16%) were improved versus 23 of 36 (64%) and 8 (22%) after bone-anchored male sling placement, respectively, after a mean of 33 months ($P > .05$).

Complications. The most common perioperative complication is urethral or bladder perforation, necessitating termination of the implant on the perforated side. However, contralateral implantation was not adversely affected, and repeat ipsilateral implantation was invariably achieved after healing of the urethral or bladder wall. Lebret and coworkers (2008) reported a perforation rate of 10%, and Hubner and Schlarp (2007) reported a rate of 18% early in their series, but a lower urethral perforation rate in more recent cases—illustrating a relatively short learning curve for optimal balloon placement near the urethral-bladder wall. The rate of temporary urinary retention was reported to be 5% (Hubner and Schlarp, 2007). Voiding was restored by removing fluid from the balloon.

Device explantation is related to balloon failure, infection, erosion, or migration. The explantation rate ranged from 10% to 58% (see Table 86-9) but decreased with experience (Hubner and Schlarp, 2007). Device removal is straightforward, because a deflated balloon can be explanted transperineally. Reported risk factors for failure and complications were prior external beam radiotherapy (Lebret et al, 2008; Gregori et al, 2010) and severe preoperative incontinence (Gregori et al, 2010). Kocjancic and colleagues (2007) reported a continence rate of 67% in nonirradiated patients compared with 36% in radiated patients.

Conclusion. The adjustable balloon (ProACT) technique appears to be a feasible procedure to improve continence in the short and medium term. Appropriate candidates include those with mild-to-moderate leakage and no previous radiation. The benefit of an adjustable system should be weighed against the need for multiple sessions to refill the balloons and with reported rates of perioperative and postoperative complications necessitating removal. Furthermore, the follow-up period in many studies includes adjustments, so long-term durability is not yet known.

The technology appears to have better results than injectable agents in men. Additional studies comparing this technology with slings and the artificial sphincter are required. The device is not commercially available in the United States.

KEY POINTS: USE OF INJECTABLES IN MALE STRESS URINARY INCONTINENCE

- The workup includes history and physical examination, urinalysis, uroflowmetry, and assessment of PVR urine. Urodynamic studies may be helpful. Cystoscopy is done to verify the status of the urethra because scarring may prevent the tissues from expanding with the bulking agent.
- Both transurethral retrograde and percutaneous antegrade techniques are feasible, with no differences in outcomes reported.
- Commonly reported injectables have included collagen and silicone microparticles. These agents show initial good results, the need for multiple treatment sessions, and deterioration of outcome over time. Reports of injectables in male patients are far few than those in female patients.
- The use of implanted adjustable silicone (ProACT) balloons appears to be a feasible technique. However, randomized trials have yet to be done, multiple sessions are needed to fill the balloons, and long-term durability is not known.

USE OF INJECTABLES FOR INCONTINENCE AFTER URINARY DIVERSION

There are increasing numbers of reports in the literature about the use of injectables after diversion. *Izes and colleagues (1997)* demonstrated in a canine study that GAX collagen injected circumferentially into the lumen of the ileocecal valve can increase the leak point pressure for up to 1 month after injection. Subsequently, *Smith and colleagues (1998b)* reported results of collagen use in four women and two men with leaking Indiana pouches. These authors injected a mean of 16 mL circumferentially into the ileocecal junction to obtain visual closure of the bowel lumen. After a mean follow-up of 26 months, five of the six patients remained dry.

Guys and colleagues (2002) reported on the use of Macroplastique for other leaking continent catheterizable channels. They injected 6 patients (4 appendix and 2 ileum) with a mean of 6 (3 to 8) mL. One had a second injection after 3 months. Four of 6 were continent after a mean of 11 (8 to 18) months. *Halachmi and colleagues (2004)* reported cure in 3, improvement in 1, and no change in 1 of 5 patients with stoma leakage. *Prieto and colleagues (2006)* treated 14 patients with leaking stomas with 2 to 6 mL (mean 3.7 mL) of DHA. With a mean follow-up of 1 year, 10 were dry after one injection, 1 was dry after two injections, and in 3 the treatment failed. *Welk and coworkers (2008)* achieved success in 2 of 4 patients with DHA injections. *Kass-Ilya and colleagues (2015)* reported a 50% success rate in 24 patients after a mean of 30

months with use of Macroplastique. Three were dry and 9 were improved. Five of the 9 improved patients went on to surgery at a mean of 41 months. Injectable agents appear to be a benefit in more than 50% of reported patients and may obviate or delay surgical revision.

Injectables have been rarely reported in women after neobladder construction. *Tchetgen and colleagues (2001)* reported on 3 women with SUI after cystectomy and orthotopic neobladder. An average of two injections were given, with a cure in 1 patient, improvement in 1, and no change in 1. *Wilson and colleagues (2004)* administered transurethral collagen to 11 patients and pyrolytic carbon-coated zirconium beads to 1 patient with SUI after cystectomy and neobladder. After a mean of 22.5 months, 2 patients (16.7%) were dry, although they continued to have urinary frequency. Four patients (33.3%) were improved and 6 were unchanged. The authors concluded that the treatment response was not optimal or durable.

New-onset vesicovaginal fistula was reported in two patients who had undergone collagen injection for SUI after cystectomy and neobladder (*Pruthi et al, 2000*). Both patients underwent transvaginal fistula repair with pubovaginal sling.

To date, the success of injectables for neobladder urethral incontinence is limited.

Catheterization

Increasing Intravesical Pressure or Facilitating Bladder Contractility

Additional Therapies for Storage and Emptying Failure: Circumventing the Problem

Summary

Disorders of the storage and emptying phases of micturition result in voiding dysfunction and often lead to bothersome urinary symptoms. The location of the storage or emptying failure may occur at the bladder, the bladder outlet, or a combination of both. Storage failure originating from the bladder results from poor bladder compliance, decreased capacity, detrusor overactivity (DO), and/or altered bladder sensation. Failure of the bladder outlet to store urine is due to an incompetent closure mechanism. Emptying disorders can similarly be classified by location. At the bladder level, impaired or absent detrusor contractility leads to emptying failure. At the bladder outlet, emptying difficulties are caused by anatomic obstruction or sphincter dyssynergia/dysfunction. In previous chapters, numerous therapies for bladder storage and emptying failure have already been discussed, illustrating the complexities of voiding dysfunction management. A comprehensive summary of these treatment options can be found in Boxes 70-3 and 70-4 in Chapter 70.

This chapter will cover additional therapies to improve bladder storage and emptying, including contemporary augmentation cystoplasty techniques for adults, surgical and nonsurgical management of the incompetent bladder outlet, modified cystoplasty incorporating a catheterizable channel and catheterization.

ADDITIONAL THERAPIES FOR STORAGE FAILURE AT THE BLADDER LEVEL

Failure of the filling/storage phase of micturition often results in urinary symptoms of frequency, urgency, and/or incontinence. Additionally, poor bladder compliance and reduced capacity may lead to renal function deterioration. The goals of therapy for storage failure are urine accommodation in the bladder at low pressures, improved bladder capacity, decreased incontinence related to DO, and preservation of renal function.

Augmentation Cystoplasty

Augmentation cystoplasty is a well-established technique that typically involves adding an enteric segment to the bladder to increase its size. This can improve bladder compliance and capacity, preserve renal function, and minimize incontinence resulting from severe DO. Augmentation cystoplasty is performed in patients who have failed or who are not candidates for more conservative forms of intervention such as anticholinergics, intravesical instillation of medication, intravesical injection of botulinum toxin, and/or

clean intermittent catheterization (CIC). The contemporary indications for augmentation cystoplasty are narrowing with the rising efficacy of these conservative therapies, especially botulinum toxin, and their ability to improve bladder compliance and capacity (Karsenty et al, 2008). However, augmentation cystoplasty plays an important role in the management of refractory patients. In the appropriate patient, augmentation cystoplasty is an excellent treatment option that can enhance bladder function and improve patients' quality of life.

Historical Perspective

First reported in canines by Tizzoni and Foggi in 1888 (Tizzoni and Foggi, 1888), augmentation ileocystoplasty was performed in humans one year later by von Mikulicz (1889). After 1972, with the introduction of CIC and the wider use of enteric segments in urologic procedures, the technique of augmentation cystoplasty gained popularity (Biers et al, 2012). In 1982, Bramble's technique of clam cystoplasty (1982), further popularized by Mundy and Stephenson (1985), established the use of augmentation cystoplasty in the urologic community.

More recently, the number of augmentation cystoplasty procedures being performed has declined. Data from the United Kingdom show a 38% reduction in augmentation cystoplasty operations from 2000 to 2010. This reduction appears to coincide with a dramatic increase in the use of intravesical botulinum toxin (Biers et al, 2012). The decline also may be related to increasing concern for complications associated with augmentation cystoplasty, including malignancy, spontaneous bladder perforation, and metabolic changes (Schlomer et al, 2013).

Indications for Augmentation Cystoplasty

Although augmentation cystoplasty is performed less frequently today, it is still a mainstay for several important reasons in the management of patients who have failed or who are not candidates for other conservative therapies. The key indications for augmentation cystoplasty arising from storage failure at the bladder level are poor bladder compliance, reduced bladder capacity, and significant DO.

Bladder Compliance

Compliance is defined as the relationship between change in bladder volume and change in detrusor pressure. Ideally, as the

bladder fills the detrusor pressure should remain low, with little to no change as volume increases. Impaired bladder compliance can be a result of changes in the viscoelastic properties of the bladder, as seen in disease processes that increase collagen deposition in the bladder wall. These disease states include radiation cystitis or chronic inflammatory and infectious processes (i.e., genitourinary tuberculosis or schistosomiasis). Bladder compliance also can be negatively affected by neurologic diseases such as myelodysplasia and multiple sclerosis, as well as spinal cord injury (SCI). In these neurologic conditions, increases in afferent input and changes in sympathetic facilitation of bladder filling contribute to decreased compliance. Additionally, patients with lesions below the sacral cord may develop compliance issues as a result of decentralization (Reyblat and Ginsberg, 2008). It is well known that patients with poor bladder compliance and/or subsequent increases in detrusor pressures of greater than 40 cm H₂O without leakage during bladder filling are at risk for vesicoureteral reflux and upper tract deterioration (McGuire et al, 1981). Patients with poor compliance require intervention to reduce storage pressures, thereby preserving renal function. Multiple studies show that augmentation cystoplasty successfully reduces detrusor pressures and improves bladder compliance. In the literature, there is a reported 65% to 82% reduction in mean maximum detrusor pressure after augmentation cystoplasty (Khastgir et al, 2003; Quek and Ginsberg, 2003; Gurung et al, 2012). Additionally, long-term data with 6 to 14 years of postoperative follow-up show this improvement in compliance to be sustained over time (Khastgir et al, 2003; Quek and Ginsberg, 2003; Gurung et al, 2012). After augmentation cystoplasty, resolution or marked improvement in vesicoureteral reflux is also reported (Khastgir et al, 2003).

Capacity

Reduced bladder capacity, found in conjunction with poor bladder compliance and/or severe DO, is another indication for augmentation cystoplasty. Patients with significantly reduced bladder capacities are bothered by incontinence, frequent urination, and/or the frequent need to perform CIC to avoid leakage. These bothersome lower urinary tract symptoms (LUTS) negatively affect patients' social, psychological, and physical quality of life (Ku, 2006; Liu et al, 2010). Patients who have undergone augmentation cystoplasty have improvements in bladder capacity with an increase in mean cystometric capacity from 200 mL to over 500 mL postoperatively (Khastgir et al, 2003; Quek and Ginsberg, 2003; Gurung et al, 2012; Khavari et al, 2012). Additionally, after augmentation cystoplasty, patients have significant improvement in their quality of life and a 93% to 96% satisfaction rate (Khastgir et al, 2003; Gurung et al, 2012).

Detrusor Overactivity

Augmentation cystoplasty is also indicated in patients with severe DO who are refractory to anticholinergics, intravesical injection of botulinum toxin, and/or neuromodulation. DO is a urodynamic finding characterized by involuntary detrusor contractions during filling cystometry. These involuntary detrusor contractions may be solitary, phasic, or terminal and can occur in neurogenic and non-neurogenic patients. DO can result in significant urinary urgency, frequency, and/or incontinence. Patients may ultimately require augmentation cystoplasty to alleviate these symptoms. A systematic review of the literature demonstrated that patients with neurogenic DO incontinence scored lower on various health-related quality-of-life instruments measuring physical, emotional, and psychological parameters when compared to their continent counterparts (Tapia et al, 2013). Not surprisingly, urinary incontinence from neurogenic DO also negatively affects patients' sexual function (Valtonen et al, 2006). As mentioned previously, augmentation cystoplasty improves patients' quality of life substantially and has a high satisfaction rate of 93% to 96% (Khastgir et al, 2003; Gurung et al, 2012). Overall continence rates in patients with neurogenic DO also improve after augmentation cystoplasty and

range from 80% to 100% (Biers et al, 2012). Although augmentation cystoplasty is not commonly performed for idiopathic DO, data show similar continence and satisfaction rates of 78% to 90% in this population (Edlund et al, 2001).

Augmentation Cystoplasty Techniques

Many gastrointestinal tract segments have been used for bladder augmentation. These segments include ileum, sigmoid colon, cecum, and stomach. Each is associated with its own advantages and disadvantages. A more detailed discussion of various augmentation techniques and complications is addressed in Chapter 145.

Ileocystoplasty is the most common type of augmentation cystoplasty, because of the reconstructive urologist's familiarity with ileum and the ileum's ability to easily reach to the pelvis. Although hyperchloremic metabolic acidosis can occur after using ileum or colon for bladder substitution, the use of ileum for augmentation seems to result in less significant metabolic disturbances. Patients with SCI followed for over 10 years after ileocystoplasty had no evidence of metabolic abnormalities (Gurung et al, 2012). Normal electrolyte and arterial blood gas levels were also found after long-term follow-up of 25 pediatric patients with ileocystoplasty. However, 12% of these patients had mild osteopenia, which is a potential sequela of chronic acidosis (Hafez et al, 2003). Although patients may develop metabolic acidosis after ileocystoplasty or colcystoplasty, this acidosis is often clinically insignificant and only 16% require oral bicarbonate therapy (Biers et al, 2012).

Colon has also been successfully used for augmentation cystoplasty. The sigmoid can be redundant in chronically constipated neurogenic patients, is easy to position on the bladder, and has a large lumen and abundant mesenteric blood supply. One advantage of using cecum, or the ileoceccocystoplasty technique, is the ability to use the ileocecal valve along with terminal ileum to create a continent catheterizable channel (Sarosdy, 1992; Sutton et al, 1998). Disadvantages of using large bowel instead of small bowel for augmentation include more significant metabolic disturbances (Vaida et al, 2003), increased mucus production, and a theoretic heightened risk for malignancy. Before proceeding with augmentation cystoplasty, colonoscopy is recommended in all patients in whom colon will be used. Using the terminal ileum for ileoceccocystoplasty also puts patients at risk for vitamin B₁₂ deficiency. Thus, levels must be monitored over the long term.

When small or large bowel is unavailable or metabolic acidosis is present, stomach is an option for use in bladder augmentation. The advantages of gastrocystoplasty are decreased mucus production and less bacterial colonization. The popularity of gastrocystoplasty has waned with increasing awareness of associated complications. Hematuria-dysuria syndrome occurs in up to 70% of patients with gastrocystoplasty and is characterized by suprapubic pain, dysuria, bladder spasms, and hematuria. However, only 4% of patients with this syndrome will require chronic treatment with histamine-2 blockers or proton pump inhibitors (Leonard et al, 2000). Other complications include peptic ulcers in the bladder, augment perforation, hyperchloremic hyponatremic alkalosis, increased gastrin production, and malignancy (Biers et al, 2012).

Contraindications to Augmentation Cystoplasty

Augmentation cystoplasty is contraindicated in patients who have diseases of the bowel (i.e., inflammatory bowel disease, irradiated bowel, short gut syndrome) or bladder pathologic conditions that would preclude using the bladder (Sajadi and Goldman, 2012). Patients or caregivers also must be willing and able to perform CIC for the long term. A patient with a progressive neurologic disease, such as multiple sclerosis, may not have the ability to perform CIC in the future. Noncompliance with CIC puts the patient at risk for life-threatening spontaneous bladder perforation. Renal disease also may be a relative contraindication to augmentation cystoplasty. Baseline renal insufficiency can worsen with

the absorption and electrolyte changes that result from exposure of bowel to urine. However, if augmentation cystoplasty is indicated for renal impairment, renal function is expected to stabilize or improve. The series by [Ivancić and colleagues \(2010\)](#) of pediatric patients with chronic renal insufficiency undergoing augmentation cystoplasty showed either improvement or no change in renal function after surgery.

KEY POINTS: ADDITIONAL THERAPIES FOR STORAGE FAILURE AT THE BLADDER LEVEL—AUGMENTATION CYSTOPLASTY

- The goals of therapy for storage failure are urine accommodation in the bladder at low pressures, improved bladder capacity, decreased incontinence related to DO, and preservation of renal function.
- Augmentation cystoplasty is performed in patients who have failed or who are not candidates for more conservative forms of intervention such as anticholinergics, intravesical instillation of medication, intravesical injection of botulinum toxin, and/or CIC.
- Studies show that augmentation cystoplasty reduces the mean maximum detrusor pressure by 65% to 82% and this reduction is sustained over time.
- Although augmentation cystoplasty is a more invasive treatment, it can increase bladder capacity up to 500 mL and improve patients' quality of life substantially with a high satisfaction rate of over 90%.
- Although hyperchloremic metabolic acidosis can occur after using ileum or colon for bladder substitution, the use of ileum for augmentation seems to result in less significant metabolic disturbances.
- Disadvantages of using large bowel instead of small bowel for augmentation include more significant metabolic disturbances, increased mucus production, and a theoretic heightened risk for malignancy.
- For patients undergoing augmentation cystoplasty with colon, a colonoscopy is recommended in all patients preoperatively. Vitamin B₁₂ levels must also be monitored long term.
- Augmentation cystoplasty is contraindicated in patients who have diseases of the bowel (i.e., inflammatory bowel disease, irradiated bowel, short gut syndrome) or bladder pathologic conditions that would preclude using the bladder.

ADDITIONAL THERAPIES FOR STORAGE FAILURE AT THE BLADDER OUTLET

The inability to store urine can be the result of an incompetent bladder outlet arising from hypermobility of the urethrovesical junction, intrinsic sphincteric deficiency, denervation of the sphincteric musculature, or frank urethral loss because of various causes such as urethral erosion in women after prolonged urethral catheter use, radiation, or refractory urethral fistulae. When severe, this urinary incontinence can significantly affect patient's quality of life, leading to embarrassment and avoidance of social activities. The following sections will discuss alternative treatments for urine storage failure at the bladder outlet that have not been covered in depth in other chapters in this text.

Myoplasty for Storage Failure

Severe urinary incontinence from sphincteric damage after surgery or a congenital neurologic disorder is often managed by a sling procedure, artificial urinary sphincter, or urethral closure. The use of an autologous muscle transfer to form a neosphincter around the urethra has been reported in a few small clinical series. Case

reports describe transposition of the gracilis muscle to the urethra or bladder neck by transection of the distal muscle at the tibial tuberosity with preservation of the proximal neurovascular pedicle. The gracilis muscle is wrapped around either the bladder neck or the bulbous urethra and attached to itself (bulbous urethra) or the back of the os pubis (bladder neck) ensuring circumferential pressure on the urethra with electrical stimulation of the myoplasty. [Janknegt and colleagues \(1992\)](#) performed the first gracilis myoplasty in three patients with severe incontinence from trauma, in those with congenital epispadias, and after transurethral resection of the prostate. Working from both the lower abdomen and the perineum, the gracilis muscle was mobilized and transferred around the bladder neck with anchoring sutures placed in the pubic periosteum. Six weeks later a small incision in the thigh, near the proximal gracilis muscle, allowed placement of intramuscular electrode leads for electrical stimulation of the myoplasty. With follow-up of 5 to 9 months, two of three men had significantly improved continence with the stimulated myoplasty and were able to void to completion. In 1997, another small case report of three men with postprostatectomy incontinence underwent gracilis myoplasty with placement around the bulbous urethra ([Chancellor et al, 1997a](#)). Six weeks later the electrodes were implanted, with 75% subjective improvement in continence 6 months after electrical stimulation of the urethral neosphincter. There were no significant complications reported in either study. Eleven men with severe stress urinary incontinence were treated in a multi-institutional study with "dynamic" gracilis myoplasty followed by electrode implantation, with only one patient not showing some improvement in continence ([Chancellor et al, 1997b](#)). The authors emphasized the importance of muscle training through continuous electrical stimulation whereby muscle type conversion from fast-twitch to slow-twitch fibers is accomplished, providing resting tone for urethral closure. Despite these early reports showing promise for gracilis myoplasty for the treatment of sphincteric deficiency causing storage failure, no further studies have been undertaken to advance this procedure.

Urethral Compression Devices for Male Urinary Incontinence

The concept of urethral compression to manage male sphincteric incontinence was first reported in [Heister's 1750](#) surgical textbook, *Institutiones Chirurgicae*. He described the Heister penile clamp, a metal clamp worn across the base of the penis to control male urinary leakage ([Heister, 1750](#)). This closely resembles the Cunningham clamp, which is a well-known external fixed urethral compression device used today ([Fig. 87-1](#)). In 1961, [Berry's \(1961\)](#) implantable prosthetic device marked a new era of internal fixed urethral compression devices. This acrylic prosthesis, available in various configurations and sizes, was implanted via a perineal

Figure 87-1. The Cunningham clamp. (Bard Medical Division, Covington, GA.)

approach immobilizing the urethra up against the urogenital diaphragm with four steel wires. Berry's prosthetic did not gain wide usage because of issues with pain, displacement, and infection (Madjar et al, 2001). Kaufman, another pioneer in the field of post-prostatectomy incontinence treatment, described in several articles an evolution of the Kaufman internal fixed urethral compression procedure. The Kaufman I and II procedures relied on compression of the bulbar urethra using cavernous crural crossover or approximation, respectively (Kaufman, 1970, 1972). The Kaufman III procedure involved implanting a silicone gel prosthesis via a perineal approach to compress the bulbar urethra (Kaufman, 1973). Although initial results were promising, these procedures were eventually replaced with the evolution of the bulbourethral male sling and Scott's development of the implantable artificial urinary sphincter device (Scott et al, 1974), the AMS 721 (American Medical Systems, Minnetonka, MN). A thorough discussion of these contemporary surgical treatments for male sphincteric incontinence can be found in Chapter 91.

In certain male patients with urinary incontinence, external fixed urethral compression devices still play a role in management. In most cases, continence is achieved by wearing an external device around the penis that compresses the urethra between foam pads. The amount of compression can be adjusted by the patient to achieve dryness and minimize pressure-related injuries to the penis. Penile clamps are indicated for patients with sphincteric incontinence, often resulting from prostate surgery. These patients may have medical conditions that preclude them from other surgical options, or they are in the early postprostatectomy recovery period when surgical intervention is deferred. Patients should have normal bladder capacity and compliance. Additionally, external penile compression devices should be avoided in patients with impaired sensation or cognition, because these patients are more prone to pressure-related injuries to the penis. Obstruction to penile blood flow can be minimized by removing the device every 3 to 4 hours and by avoiding usage while sleeping or while having an erection. Moore and colleagues (2004) reported efficacy, comfort, and patient satisfaction with three penile compression devices: the Cunningham clamp (Bard Urological, Covington, GA), the C3 (Timms Medical Technologies, White Bear Lake, MN), and the U-Tex (Laborie Medical Technologies, Williston, VT). The study population included 12 men with postprostatectomy incontinence requiring continuous pad protection. Over 4 consecutive days, patients were randomly assigned to use either one of the three devices or pads alone as a control group. Each group wore the device or pads continuously for 4 hours (maximum time recommended for continuous usage), and pad weights were obtained before and after the study period to quantify leakage. Additionally, patients were asked to complete a questionnaire at the conclusion of the study. Urine leakage was significantly reduced by all three devices evaluated; however, the Cunningham clamp was the most effective of the three devices tested, reducing urine leakage by nearly 85%. The Cunningham clamp was also noted to reduce cavernosal blood flow significantly more than the other devices. Overall, patients rated the Cunningham clamp the most acceptable and preferable of the devices evaluated.

Female Urethral Occlusive Devices

Several female urethral meatal occlusive devices have been developed to address female stress urinary incontinence, including the CapSure (Bard Urological), FemAssist (Insight Medical, Boston, MA), and Impress (UroMed, Needham, MA) devices. These products either form a seal over the urethral meatus or create a negative pressure that increases urethral resistance, permitting urethral wall coaptation (Bellin et al, 1998). Unfortunately, due to the anatomy of the female urethra and the location of the meatus, these devices were difficult to apply and keep secured in place. Local tissue irritation and pain were also factors. Ultimately, these products did not gain widespread popularity and were pulled from the market. The future remains unclear for innovations in this type of occlusive urethral application for women.

Female urethral inserts or plugs are available and work by passively occluding the urethral outlet. They must be removed each time a patient voids and require a patient to feel comfortable with inserting such a device into the urethra itself. The first urethral insert to be approved for marketing by the U.S. Food and Drug Administration, the Reliance (UroMed) has been withdrawn from the market. The second-generation FemSoft stent (Rochester Medical Corporation, Stewartville, MN) (see Fig. 80-14 in Chapter 80) was FDA approved in 1997 and is currently available. Very little is published in the literature regarding the results of urethral inserts. However, one study by Sirls and colleagues (2002) reported the results of a 5-year, multicenter trial of 150 women with a 15-month follow-up using the FemSoft insert (2002). Pad weight testing and voiding diaries demonstrated efficacy of the insert, and patients reported overall satisfaction. Adverse events were common, but minor, and included symptomatic urinary tract infections (UTIs) in 31.3%, mild trauma with insertion in 6.7%, hematuria in 3.3%, and migration in 1.3% of women. Although widely applicable to women with stress urinary incontinence, it seems that there is a potential barrier in finding patients who are willing to instrument the urethra. Certainly, women who experience leakage only during certain predictable activities such as sports or who are not ready or interested in surgical intervention may be more willing to use a urethral insert to stay dry.

Intravaginal Incontinence Devices

The use of a mechanical device to treat female urinary incontinence dates back to Egyptian times (Edwards, 1970). Although today there are safe and effective surgical treatments for stress urinary incontinence, some women may still choose a nonsurgical treatment option for medical or personal reasons. There are numerous intravaginal devices designed to support the anterior vaginal wall and urethrovesical junction, thus improving urethral closure and resistance to increases in intra-abdominal pressure (Bhatia and Bergman, 1985; Komesu et al, 2008). These devices include tampons, contraceptive diaphragms, pessaries, and pessary-like devices. In the literature, there is a paucity of robust clinical data describing the efficacy of pessaries for treatment of stress urinary incontinence. Most of the studies available are limited by small numbers and short-term follow-up (Nygaard, 1995; Donnelly et al, 2004; Farrell et al, 2007).

More recently, Richter and associates (2010) published the results of the Ambulatory Treatments for Leakage Associated with Stress Incontinence (ATLAS) trial, a multicenter, randomized control trial of 446 women with 12 months of follow-up. The objective of the study was to compare the efficacy of a continence pessary to evidence-based behavioral therapy or combination therapy in treating women with stress incontinence. Outcomes were based on responses to the Patient Global Impression of Improvement and the stress incontinence subscale of the Pelvic Floor Distress Inventory. Patients had greater satisfaction (75% vs. 63%, $P = .02$) and less bothersome incontinence symptoms (49% vs. 33%, $P = .006$) in the behavioral therapy group compared to the pessary group at 3 months. Combination therapy was better than pessary alone, but not behavioral therapy alone. However, these group differences were not sustained at the 12-month mark, although all treatment groups continued to report greater than 50% satisfaction rates.

In general, the advantages of a continence pessary or comparable intravaginal device are the applicability to a broad spectrum of patients with stress or mixed urinary incontinence, the ease of device fitting in the office without cumbersome or invasive testing, the flexibility of wearing the device for predictable activities that bring on incontinence, the mild side-effect profile, and the ability of the device to manage bothersome prolapse symptoms in addition to incontinence. The disadvantages of a continence pessary can be difficulty with insertion and removal of the device for periodic cleaning, vaginal discharge, odor and/or irritation, dislodgement, and the inability of the device to address intrinsic sphincter deficiency or appropriately transmit pressure to a fibrotic urethra.

Bladder Outlet Closure: Functional and Complete

In certain instances, when other surgical interventions have failed, urethral or bladder neck closure is necessary to treat refractory incontinence. These neurogenic and non-neurogenic patients are those with urethral erosion, severe stress incontinence, bladder neck incompetence, or difficult urethral fistulae. One familiar clinical scenario is that of a neurogenic female patient managed with a long-term indwelling urethral catheter. Over time, the catheter balloon causes pressure necrosis and urethral/bladder neck destruction. The patient is left with a very patulous, incompetent outlet and suffers with severe urinary incontinence. [Chancellor and associates \(1994c\)](#) reported their results with **functional bladder neck closure using an obstructing autologous pubovaginal sling** in 14 female patients with neurogenic, end-stage bladders and a destroyed bladder outlet from chronic indwelling Foley use. All women had an intact bladder neck and at least 1 cm of viable proximal urethra. With a mean follow-up of 24 months, all patients had success with minimal incontinence and a low rate of complications. **This type of functional bladder neck closure avoids complete closure of the urinary system, providing a “pop-off” valve for leakage at higher pressures and allows access for possible future instrumentation.** In this type of scenario, in which the sling is meant to obstruct the bladder outlet, autologous or cadaveric slings are superior to mesh slings, which would be much more likely to erode into the urethra. However, several studies have described using mesh slings in a “spiral” fashion to wrap the urethra circumferentially for refractory patients with stress urinary incontinence ([Rutman et al, 2006](#); [Mourtzinou et al, 2008](#); [Rodriguez et al, 2010](#)). This tech-

nique, first described by [Rutman and associates \(2006\)](#), involves a transvaginal urethrolisis to gain access to the urethra circumferentially. A polypropylene mesh sling with sutures attached to each of the ends is completely wrapped around the urethra, crossing at the ventral urethra, and then the ends are passed retropubically and tied above the fascia. Success of 72% to 87%, or overall improvement in symptoms, was reported in these small series with few complications noted ([Rutman et al, 2006](#); [Mourtzinou et al, 2008](#); [Rodriguez et al, 2010](#)). Further discussion regarding sling procedures can be found in Chapter 84.

When preservation of a functional bladder outlet is not a viable option, transvaginal, transabdominal, or combined bladder neck closure along with LUT reconstruction to the abdominal wall is indicated. **It should be noted that closure of the bladder neck is more challenging than a simple cystorrhaphy. The bladder neck is hyperactive in neurogenic patients, and stress is placed on the bladder neck closure with every voiding reflex.** It is imperative to have a multilayer, watertight closure and use postoperative drains to avoid fistula formation ([Fig. 87-2](#)). Additionally, an adequate time of continuous bladder drainage and use of anticholinergics will limit the stress on the bladder neck suture line.

[Levy and colleagues \(1994\)](#) reported a 40% success rate using a transvaginal bladder neck closure. They subsequently modified the approach, using a combined transvaginal-transabdominal approach, and reported a 100% success rate at a mean 16-month follow-up for the subsequent 10 patients. [Shpall and Ginsberg \(2004\)](#) reported on 39 patients who underwent a combined transabdominal bladder neck closure and various continent and incontinent diversions. At a mean of 37 months, 6 patients (15%) developed fistulae; however,

Figure 87-2. A, After injection of normal saline solution into the anterior vaginal wall, an incision is made around the urethral opening to create the vaginal wall flap. B, The urethral meatus is dissected free, and the vaginal wall flap is created. C, The bladder neck wall musculature is vertically closed in a running fashion after the mucosal layer has a watertight closure. D, The final muscular layer is closed in a horizontal fashion and rotated superiorly behind the pubis. E, The vaginal epithelium is advanced over the entire defect and closed with a running suture.

4 patients underwent successful repair, for an overall 95% cure rate. Additionally, O'Connor and colleagues (2005) reported on 35 patients with a mean 79-month follow-up who underwent a transabdominal bladder neck closure for refractory incontinence. They were initially successful in 28 (83%) patients, with an overall 94% cure rate after one revision. Most recently, Kavanagh and associates (2012) reported with a median follow-up of 69 months on 28 pediatric or adolescent patients who underwent concomitant transabdominal bladder neck closure with enterocystoplasty and Mitrofanoff diversion. Bladder neck closure was successful in 96.4% of patients with only one requiring repair of a postoperative vesicovaginal fistula. In addition, there was no evidence of progressive or new hydronephrosis in their cohort. **Ultimately, closure of the bladder outlet with simultaneous LUT reconstruction is often required and can be highly successful in certain refractory patients who have failed other surgical treatments for their destroyed bladder outlet.** Bladder neck closure is definitive, and patients need to understand the importance of adhering to bladder drainage, such as CIC via their catheterizable channel, to avoid the complication of spontaneous bladder perforation. Although rare, concerns also arise over the potential difficulty in accessing the bladder acutely because of an emergency situation or possible stomal stenosis; reported rates of stenosis are 6% to 19.5% (Welk et al, 2008; Leslie et al, 2011; Ardelt et al, 2012). One group discusses equipping all their patients with MedicAlert bracelets and instructing them on how to decompress their bladder if need be via percutaneous needle aspiration (Kavanagh et al, 2012).

KEY POINTS: ADDITIONAL THERAPIES FOR STORAGE FAILURE AT THE BLADDER OUTLET

- The use of a stimulated autologous muscle transfer to form a neosphincter around the urethra, a gracilis myoplasty, has been reported in a few small clinical series. Despite early reports showing promise for the treatment of sphincteric deficiency causing storage failure, no further studies have been undertaken to advance this procedure.
- Penile clamps are indicated for patients with sphincteric incontinence, often resulting from prostate surgery. These patients may have medical conditions that preclude them from other surgical options, or they are in the early post-prostatectomy recovery period when surgical intervention is often deferred. Normal bladder capacity and compliance are relative requirements, and use of these devices should be avoided in patients with impaired sensation or cognition, because these patients are more prone to pressure-related injuries to the penis.
- Female occlusive urethral devices have been developed, but because of the female urethral anatomy may be difficult to apply, insert, or maintain. The ideal occlusive urethral device for women does not exist.
- Numerous intravaginal devices exist that support the anterior vaginal wall and urethrovaginal junction, thus treating stress urinary incontinence by improving urethral closure and resistance to increases in intra-abdominal pressure.
- In certain instances, bladder outlet closure is necessary to treat refractory urinary incontinence. Functional urethral closure with an autologous pubovaginal sling avoids complete closure of the urinary system providing a pop-off valve for leakage at higher pressures and allows access for future transurethral instrumentation.
- Closure of the bladder neck is more challenging than a simple cystorrhaphy. The bladder neck is hyperactive in neurogenic patients and stress is placed on the bladder neck closure with every voiding reflex leading to the most common complication, fistula formation.

ADDITIONAL THERAPIES FOR EMPTYING

Continent Catheterizable Channels

Some neurogenic patients require CIC to empty but have difficulty accessing the native urethra. This can be the case in patients with limited upper extremity dexterity or in female patients who are wheelchair-bound and find it troublesome to position themselves for CIC. Often, these patients depend on caregivers to assist them with CIC, have impaired self-esteem and body image, and ultimately desire more independence. Walsh and colleagues (2004) studied quadriplegic female patients who underwent surgery for creation of continent catheterizable channels. The authors show that these patients had significant improvements in quality of life measures and had increased efficiency in catheterizing (decrease in time to catheterize from 27 (range 10 to 40) to 7.8 (range 1 to 15) minutes). Another study by Zommick and associates (2003) reviewed outcomes of continent LUT reconstruction in 21 patients with cervical-level SCIs and varying degrees of upper extremity dexterity. These patients, who all underwent creation of a continent urinary stoma, reported improvements in quality of life because of eradication of urinary drainage bags, increased continence, more freedom, and improved body image. In addition, a majority (95%) were able to maintain CIC long-term by themselves or with the help of a caregiver.

Urethral loss also can necessitate creation of a continent catheterizable channel to maintain bladder access and continence. In addition to neurogenic patients, patients with non-neurogenic benign disease processes such as recalcitrant bladder neck contracture, urethral loss from stricture or radiation damage, and refractory urethral fistulae are candidates for continent LUT reconstruction. Finally, neurogenic patients undergoing augmentation cystoplasty who also have severe incontinence from various causes, including urethral erosion, severe stress incontinence, or bladder neck incompetence, will need concomitant bladder outlet surgery at the time of augmentation cystoplasty and formation of a continent catheterizable channel.

Various techniques, many using the flap-valve mechanism for continence, have been described: the Mitrofanoff appendicovesicostomy (Mitrofanoff, 1980); a transverse ileal tube (Yang-Monti) (Yang, 1993; Monti et al, 1997); tapered ileum implanted into a serous-lined extramural tunnel (Abol-Enein and Ghoneim, 1999); and the ileocecostoplasty, which uses the ileocecal valve to provide continence (Sarosdy, 1992; Sutton et al, 1998) (Fig. 87-3). These channels are not free of complications, and long-term issues with catheterization, incontinence, and stomal stenosis can occur. A large retrospective study by Leslie and associates (2011) analyzed the long-term outcomes of 169 pediatric patients who had either undergone a Mitrofanoff appendicovesicostomy or a transverse ileal, or Monti, tube. The authors report a 39% revision rate (8% stricture, 4% prolapse, 10% incontinence, and 17% stomal stenosis at skin level). Despite revisions, 96% of channels were still functional at last follow-up. A comprehensive review of the literature on continent catheterizable channel techniques using the flap-valve mechanism shows comparable mean complication rates of 13.3% incontinence and 19.5% stomal stenosis (Ardelt et al, 2012). The choice of continent channel technique is often influenced by the patient's anatomy and the surgeon's preference.

CATHETERIZATION

Catheterization, in its many forms, is an effective method of bladder emptying and is a useful adjunct when efforts to increase intravesical pressure and/or decrease outlet resistance have been unsuccessful. In addition, for those patients who have filling/storage failure caused by bladder overactivity and/or sphincteric incontinence, catheterization also may be used if the dysfunction can be converted solely or primarily to one of emptying by non-surgical or surgical means (Wein and Barrett, 1988). The common goals, irrespective of the mode of catheterization, are to provide

Figure 87-3. Diagram of the continent ileocecal augmentation cystoplasty with the bowel segment used (right cecum and distal ileum) in the upper right corner and a view of the bivalved bladder in the lower right corner. (From Sutton MA, Hinson JL, Nickell KG, et al. Continent ileocecal augmentation cystoplasty. *Spinal Cord* 1998;36:246–51.)

KEY POINTS: ADDITIONAL THERAPIES FOR EMPTYING—CONTINENT CATHETERIZABLE CHANNELS

- Indications for creation of a continent catheterizable channel include difficulty with catheterizing per urethra (i.e., diminished upper extremity dexterity, inability to easily access the urethra), urethral loss from scarring, radiation, or fistula formation; and urethral incompetence and severe leakage in patients requiring bladder outlet closure.
- These continent catheterizable channels are not free of complications and long-term issues with catheterization, incontinence, and stomal stenosis can occur.

low-pressure storage, preserve continence, avoid renal deterioration, minimize complications, and maintain quality of life.

Indwelling urethral catheters are generally used for short-term bladder drainage, and careful use of a small-bore catheter for a short time is unlikely to adversely affect the ultimate outcome, especially if used in the initial bladder management in SCI (Lloyd et al, 1986). Long-term bladder drainage may be obtained by intermittent catheterizations or by an indwelling suprapubic or urethral catheter. Historically, the most appropriate form of bladder drainage in patients requiring prolonged bladder management has been debated. Most studies evaluating the different forms of long-term bladder management have been retrospective and in patients with SCI, because they represent the majority of patients requiring long-term catheterization. The main area of controversy concerns whether long-term indwelling catheterization in neurologically impaired patients is associated with an inferior outcome compared to CIC, specifically regarding urinary tract complications or quality of life.

Although CIC is currently the preferred management for patients requiring prolonged bladder drainage, it is a recent innovation. Intermittent catheterization was first introduced as a sterile procedure in 1949 by Guttman and, at the time, challenged the beliefs of most urologists (Guttman, 1949; Guttman and Frankel, 1966).

It was not until Lapidès and colleagues (1972) introduced the concept of clean intermittent catheterization that widespread usage became more common. As the popularity of CIC grew, long-term indwelling catheterization was condemned, based on both infectious risks and a perceived increased risk for other urologic complications. Jacobs and Kaufman (1978) reported that there were more renal and other urologic complications with long-term (>10 years) catheterization use than with short-term use. Hackler (1982) also reported accelerated renal deterioration in patients with SCI managed with long-term suprapubic catheterization. McGuire and Savastano (1984) reported a poorer outcome in women with an indwelling urethral catheter than in those on CIC after 2 to 12 years. Of 13 in the catheter group, 54% had adverse changes on intravenous pyelography, as opposed to 0% in the CIC group. Other urologic complications were also more frequent and severe in the catheter group.

Conversely, more recent investigations have suggested the complications from chronic indwelling catheters may be lower than previously thought. Sekar and coworkers (1997) reported on the effect of different bladder management methods in 1114 patients with SCI using total and individual kidney–effective renal plasma flow as the primary outcome measure. Follow-up was relatively long with 51.3% followed for 0 to 3 years, 40% for 5 years, and 20% for at least 10 years. Unfortunately, many issues such as unclear methods of urinary management at discharge, incomplete data on approximately 200 patients, and the fact that most men who were discharged using CIC later changed to condom catheter drainage, weaken the authors' conclusions that there was very little change in renal function over time in patients using different bladder management methods. Dewire and associates (1992) reviewed the course of 32 quadriplegic patients managed with, and 25 without, an indwelling catheter. The groups were roughly comparable, and follow-up was for 10 years or longer. The incidences of upper and LUT complications and renal deterioration were not significantly different. Chao and coworkers (1993) did a similar review on 32 patients with SCI with an indwelling urethral (14 patients) or suprapubic catheter (18 patients) versus 41 patients without. Follow-up was 20 years or longer. Although the catheterized group had a higher prevalence of upper tract scarring and caliectasis, no significant differences were found in other indices of renal function or in the prevalence of other urologic complications. Jackson and DeVivo (1992) reported on the results of indwelling catheterization in 108 women (with SCI) followed for 2 to 5 years (56 women), 6 to 9 years (31 women), and 10 or more years (21 women) after injury. Compared with the male population, the majority of which were being managed by condom drainage, there was no difference in upper or lower tract complications. MacDiarmid and colleagues (1995) reported on suprapubic catheterization in 44 patients with SCI, with follow-up ranging from 12 to 150 months (mean 58 months). They reported that no patient had renal deterioration or vesicoureteral reflux and that the incidences of incontinence, infection, and calculi were acceptable. Of the patients, 11% had leakage, 100% had bacteriuria, 41% developed bladder calculi, 7% developed renal calculi, 36% developed episodes of catheter blockage, and only 5% had gross hematuria requiring hospitalization and bladder irrigation.

Upper tract and infectious complications often occur regardless of whether intermittent or indwelling catheterization is used. Although bacteriuria is common in all forms of bladder catheterization, symptomatic infection is not. The presence of asymptomatic bacteriuria does not usually require treatment and should be distinguished from an invasive, symptomatic UTI. Treatment of asymptomatic bacteriuria has not proved beneficial, and the use of continuous prophylactic antibiotics is rarely indicated (Gribble and Puterman, 1993). Nevertheless, infectious complications are the most common complications associated with prolonged catheterization, and procedures such as frequent catheter changes should be considered to reduce these complications (Weld and Dmochowski, 2000; Wyndaele, 2002). Much interest has recently been generated with catheter-associated infections in hospitalized patients. Under new rules by the Centers for Medicare and Medicaid

Services, hospitals will not be compensated for catheter-associated UTIs, causing many hospitals to intensify their efforts in implementing preventive measures (Saint et al, 2009). For more information regarding bacteriuria and catheter-associated UTI see Chapter 12.

More recent studies have shown the superiority of CIC over long-term indwelling catheter drainage. Weld and Dmochowski (2000) reported a retrospective review of 316 patients with SCI with a mean follow-up of 18.3 years. Bladder management methods included chronic urethral catheterization in 114 patients, CIC in 92, spontaneous voiding in 74, and suprapubic catheterization in 36. Complications were recorded in terms of infectious complications (epididymitis and pyelonephritis), renal and bladder calculi, urethral complications (stricture and periurethral abscess), and radiographic abnormalities (vesicoureteral reflux and abnormal urographic findings). Overall, there were 398 complications recorded, of which 236 developed in 61 patients (53.5%) on chronic urethral catheterization, 48 in 16 patients (44.4%) on suprapubic catheterization, 57 in 24 patients (32.4%) who voided spontaneously, and 57 in 25 patients (27.2%) on CIC. Separate bar graphs for each type of complication seem to confirm the overall superiority of CIC as the least problematic long-term form of bladder management (Fig. 87-4).

The exact cause of upper tract deterioration in patients with long-term indwelling catheters is unclear because the bladder should be well drained by a catheter; however, it is likely related to chronic "occult" or subclinical DO in the face of sphincteric dyssynergy providing a functional obstruction. Regardless of the cause, it is clinically heralded by the development of poor detrusor compliance demonstrated on urodynamic studies. Weld and colleagues (2000) reported the effects of bladder management (CIC, spontaneous voiding, or chronic indwelling urethral catheterization) on bladder compliance and changes in compliance with time in patients with SCI. Logistical regression analysis of compliance versus bladder management and interval since injury revealed that CIC and spontaneous voiding were more associated with normal compliance than indwelling urethral catheterization. Poor compliance was statistically associated with vesicoureteral reflux, radiographic upper tract abnormalities, clinical pyelonephritis, and upper tract calculi. The authors concluded that CIC protects bladder compliance in patients with SCI and helps prevent poor compliance and upper tract complications with time. Jamil and associates (1999) reported on ambulatory urodynamics in 30 patients with SCI whose bladders were managed with an indwelling urethral catheter. They found that freely draining indwelling catheters did not guarantee consistently low intravesical pressure. Of 30 patients, 11 demonstrated intermittent detrusor contractions causing intravesical pressure increases greater than 40 cm H₂O for up to 4.5 minutes. These patients had used an indwelling catheter for a mean of 14.3 years (range, 4 to 36 years). Renal scarring was observed in 9 patients, and, of these, 6 were in the group with the abnormal bladder contractions, whereas only 5 of 21 patients with normal kidneys had such pressure rises. The clinical correlate emphasized by the authors was their belief that maintenance of a compliant bladder and suppression of high-pressure contractions in chronically catheterized patients may play a role in the prevention of renal deterioration. Kim and associates (1997) demonstrated in a retrospective analysis that anticholinergic medications can reduce the incidence of hydronephrosis, improve bladder compliance, and decrease leak point pressures in patients with chronic catheters. The role of anticholinergics with various forms of prolonged bladder management and in the prevention of upper tract complications has not yet been clarified (Feifer and Corcos, 2008).

There is certainly some controversy about the classic teaching that long-term continuous bladder catheterization in patients with neurogenic bladder dysfunction should be avoided at all costs. There are clearly some situations in which such management is desirable and necessary. Studies that purport to compare methods of management regarding lower and upper tract complications are often flawed and prevent total acceptance of their conclusions. In

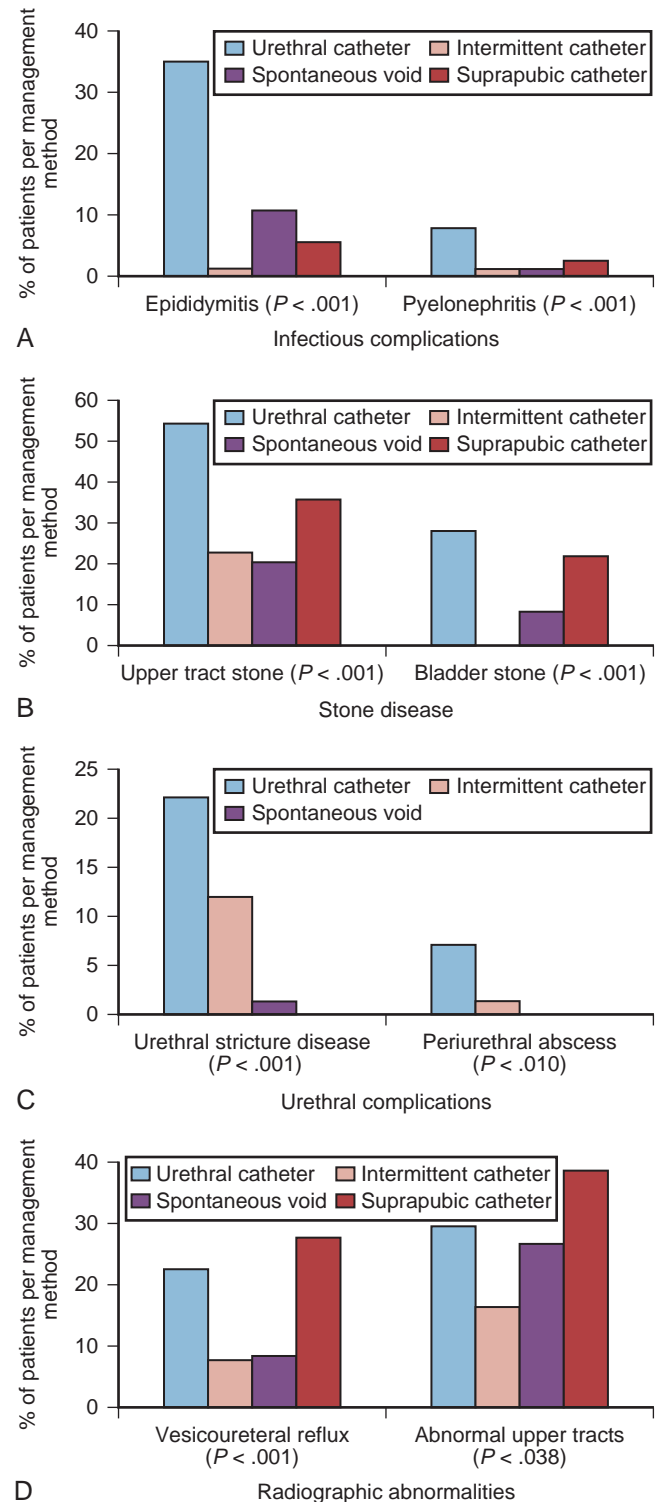

Figure 87-4. Complications related to specific bladder management methods: infectious (A); stone disease (B); urethral (C); radiographic abnormalities (D). (Modified from Weld KJ, Dmochowski RR. Effect of bladder management on urological complications in spinal cord injured patients. *J Urol* 2000;163:768–72.)

the absence of a prospective, randomized study or acceptable retrospective data, patient and family comfort, convenience, and quality of life must be strongly considered in the decision of which method of catheterization will be employed. Regardless of which method is used, periodic upper and lower tract evaluation using renal ultrasonography and cystoscopy should be considered in all patients who require prolonged bladder management. Finally, the use of

urodynamics to monitor the bladder in neurologically impaired individuals is controversial. At a minimum, we believe that urodynamics should be performed after the initial neurologic injury is stable and whenever any significant changes in continence or voiding function occur. The initial urodynamics is useful to direct early bladder management, while subsequent urodynamics evaluations are performed to determine if LUT changes, such as the development of dyssynergia, have occurred.

Clean Intermittent Catheterization

CIC has proved to be the most effective and practical means of attaining a catheter-free state in the majority of patients who are unable to empty their bladders spontaneously. CIC has revolutionized the treatment of difficult cases of neuromuscular dysfunction of the LUT by providing a safe and effective method that preserves the independence of the patient to empty the LUT in cases in which continence has been achieved pharmacologically or surgically, producing total or partial urinary retention. For example, without CIC, the successful outcomes achieved using augmentation cystoplasty or continent urinary diversion would have never been achieved. CIC is based on a theory proposed by Lapides that high intravesical pressure or bladder overdistention is primarily responsible for the development of UTI, not the bacteriuria itself. Theoretically, reduced blood flow to the bladder can lead to increased host susceptibility to bacterial invasion and UTI. Bacteria introduced by CIC would be neutralized by the host, and relatively sterile urine would be maintained as long as bladder distention and high intraluminal pressures were avoided. The long-term efficacy and safety of such a program has been demonstrated by Lapides and others (Weld and Dmochowski, 2000).

Whereas indwelling catheter drainage requires little input from the patient, a cooperative, well-motivated patient or family is a requirement for CIC. The patient must have adequate hand control, or a family member must be willing to perform the catheterization. In addition, there must be adequate urethral exposure. Graham (1989) reported on the factors required to successfully develop a catheterization program for patients with functional limitations, which commonly exists in patients with neurogenic bladder dysfunction. It is advantageous to have a dedicated nurse who instructs the patients and families in the catheterization regimen; provides them with understandable written instructions to refresh their memory regarding technique, precautions, and danger signals; and provides continuing support for patients and families who call with questions or problems regarding their regimen. Many patients are initially reluctant to perform any procedure on their own genitalia. Patients need a thorough explanation of the advantages of CIC along with assurances that it is simple and that it will not tie them to their houses or to an absolute time schedule. Additionally, proper selection of equipment for the patient's intelligence and financial level will increase patient acceptance of and compliance with a self-catheterization program. Patients who are reticent initially are continually amazed by the ease with which such a regimen is established. Successful CIC is intimately associated with patient compliance, and therefore patients should be monitored periodically to ensure catheterization is performed properly. Of note, CIC should be used cautiously in patients known to have autonomic dysreflexia.

Intermittent catheterization may be performed by clean, aseptic, or sterile techniques (Hudson and Murahata, 2005). CIC often includes reusing a catheter several times before disposal. It is washed, generally with soap and water, and allowed to air-dry before storage. When reusing catheters, some have advocated boiling or microwaving for sterilization (Douglas et al, 1990). In April 2008, in an attempt to decrease the incidence of UTIs in patients performing intermittent catheterization, Medicare policy regarding intermittent catheterization changed. Any patient requiring intermittent catheterization may obtain up to 200 sterile catheters per month for one-time use. This change in policy has negated the need for reusing catheters in most patients, but it still may be necessary in patients without insurance coverage or other financial limitations. For adult patients, catheterization is

typically performed at a minimum of every 4 to 6 hours to minimize bacterial dwell time. CIC may need to be more frequent if large volumes of fluid are ingested. In most cases, catheterizations should be timed to maintain bladder volumes below the normal 400- to 500-mL capacity to minimize bladder wall pressure. Even smaller volumes may be required if they have poor detrusor compliance. Catheter choice is variable, but a 12- to 16-Fr soft catheter may be used for males and a short (6-inch "female") 12- to 16-Fr catheter for females. Note that rigid catheters have the potential to injure the urethra in insensate males because they may not "make the bend" at the prostate, causing a false passage such that CIC may be quite difficult or impossible. Larger catheters may be required in patients with a prior bowel augmentation or those who require bladder irrigation. In men, hydrophilic coated catheters have been found to reduce the incidence of UTI and hematuria and have higher patient satisfaction rates than conventional plastic catheters (Vapnek et al, 2003; De Ridder et al, 2005). Patients with recurrent UTIs, despite the use of single-use sterile catheters, may obtain sterile catheter kits for sterile intermittent catheterization. Anticholinergic medication should be considered when urine leakage occurs between catheterization intervals or if high storage pressures develop. Wyndaele (2002) reported that trauma from catheterization occurs frequently, but effects are usually not long-standing, and urethral stricture and false passages are more common the longer that CIC is employed.

Continuous Catheterization

Long-term indwelling catheters should be considered when anatomic, functional, or familial limitations prohibit performance of intermittent catheterization. Continuous catheterization also may be indicated in patients with complications from persistent incontinence or autonomic dysreflexia, despite therapy or when a small bladder capacity prohibits effective CIC. Long-term catheterization may be accomplished by either a urethral or suprapubic catheter. The basics of urethral catheterization, including the technique of suprapubic tube (SPT) insertion are covered in Chapter 6.

In males, the benefits of an indwelling SPT over urethral catheterization include a lower incidence of epididymitis and urethral stricture disease (Weld and Dmochowski, 2000) and preserved sexual function (Rutkowski et al, 1995) (see Fig. 87-4). Overall, suprapubic catheters have been associated with high rates of patient satisfaction. Barnes and associates (1993) concluded that long-term suprapubic catheters were well tolerated by patients with neuropathic bladders. Based on the replies of 32 patients who expressed an opinion, 84% were satisfied; however, the follow-up was short (mean 23 months), and in 2 of 12 patients assessable at over 2 years, creatinine levels increased. Other problems occurred, including recurrent catheter blockage in 38%, recurrent symptomatic urinary infections in 23%, and displaced catheters requiring reinsertion in the operating room in 15%. Urethral leakage occurred in 8 of 14 females with a suprapubic catheter alone and in 6 of 16 males. Patients using a suprapubic catheter must be warned that urinary incontinence may commence or worsen in the setting of sphincteric incontinence or reflex DO, because active opening of the sphincteric unit will occur in the absence of dyssynergia. Sheriff and associates (1998) discussed the clinical outcomes in a satisfaction survey of 185 patients with neuropathic bladder dysfunction treated with long-term suprapubic catheterization (follow-up, 3 to 68 months; mean, 24 months). The authors reported an 82% satisfaction rate; however, the main reason for this SPT procedure was failed CIC from poor hand function. In addition, only 103 of the 185 patients filled out the satisfaction questionnaire, and only 8 patients had a suprapubic catheter for longer than 2 years. Complications in this group included 5 patients with a small bowel injury during insertion, 2 with significant hemorrhage, 2 requiring catheter repositioning, 1 requiring reinsertion because of dislodgement, 8 with persistent incontinence, and 18% with recurrent catheter blockage. Bacteriuria existed in 98% of the patients, but recurrent symptomatic infection occurred in only 4%. More recently, Ahluwalia and colleagues (2006) reported a

satisfaction rating of 71% among 219 patients having indwelling suprapubic catheters for greater than 50 months.

A controversial issue, common to all long-term indwelling catheters, is the development of bladder cancer. The long-term risk of carcinoma in the patient with SCI with a chronic catheter has been estimated to be 8% to 10% (Locke et al, 1985; Delnay et al, 1999). Kaufman and colleagues (1977) were among the first to recognize that patients with SCI and chronic indwelling catheters had an increased incidence of bladder cancer, particularly squamous cell carcinoma (SCC). Several others reported similar findings (Chao et al, 1993; Stonehill et al, 1996). Since these reports, the association between chronic indwelling catheterization and the development of bladder carcinoma has been debated. **No associations with intermittent catheterization have been identified.** Chronic inflammation is the most likely causative factor and may be caused by the indwelling catheter itself, bladder calculi, and/or recurrent infections. It is not clear whether earlier treatment of these conditions or better follow-up will lessen the risk for bladder carcinoma. A mechanism for the development of bladder carcinoma secondary to long-term inflammation was described by Wall and colleagues, (2001). According to their report, inducible nitric oxide synthase expressed by inflammatory macrophages in areas of chronic inflammation may lead to the formation of potentially carcinogenic nitrosamines in the bladder. For more on the development of carcinoma and the associations with SCI and chronic catheterization, see Chapter 75.

When SCC is identified in patients with SCI, it is often advanced and commonly fatal; however, routine screening cystoscopy for at-risk patients with SCI is controversial. Although some authors suggest that screening cystoscopy conveys a survival advantage by identifying bladder cancer at an earlier stage (Navon et al, 1997), others have found no advantage for screening (Yang and Clowers 1999; Hamid et al, 2003). Cytologic examination, although commonly performed, is not useful for detecting SCC (Bejany et al, 1987). Additionally, SCC may not always be cystoscopically detectable (Kaufman et al, 1977). For this reason, routine random biopsies have been advocated by some (Stonehill et al, 1996). Despite the lack of data in patients without SCI, most urologists recommend all patients with chronic catheters undergo annual screening, generally starting after 8 years (Stonehill et al, 1996). Gross hematuria has been reported by several investigators as the most common manifesting symptom for patients eventually diagnosed with bladder cancer (Hess et al, 2003). Despite the disparate opinions regarding screening, certainly all would agree that patients with new-onset gross hematuria should be evaluated with upper tract imaging, urinary cytologic studies, cystoscopy, and perhaps random biopsies. Other patients to consider for close surveillance should include patients with known risk factors for the development of carcinoma, such as recurrent UTIs or recurrent bladder stones.

INCREASING INTRAVESICAL PRESSURE OR FACILITATING BLADDER CONTRACTILITY

External Compression (Credé) and Valsalva Maneuver

The Credé maneuver (manual compression of the bladder) is most effective in patients with decreased bladder tone who can generate an intravesical pressure greater than 50 cm H₂O and have decreased bladder outlet resistance (Wein and Barrett, 1988). The technique of voiding by the open-handed Credé method involves placement of the thumbs of each hand over the area of the anterior superior iliac spines and the digits over the suprapubic area, with slight overlap at the fingertips. The slightly overlapped digits are pressed into the lower abdomen and when they are located behind the symphysis are pressed downward to compress the fundus of the bladder. For some patients, this maneuver can be accomplished more efficiently by using a closed fist of one hand or a rolled-up towel. Straining as the Credé maneuver is applied is generally counterproductive because this increases intra-abdominal pressure and causes bulging of the abdominal wall, which then tends to lift the compressing hands off the fundus of the bladder.

KEY POINTS: ADDITIONAL THERAPIES FOR EMPTYING—CATHETERIZATION

- Catheterization is an effective tool in promoting bladder emptying and also may assist patients with filling/storage failure resulting from overactivity and/or sphincteric incontinence, especially if the bladder can be converted solely or primarily into a storage organ using either medical or surgical means.
- Whether long-term indwelling catheterization is inferior to CIC remains a main area of controversy, specifically regarding urinary tract complications and quality of life.
- Asymptomatic bacteriuria is common in catheterized patients and does not require treatment unless the patient becomes symptomatic.
- Periodic surveillance should be considered in patients with chronic catheters, because elevated bladder pressures, poor bladder compliance, and upper tract deterioration may develop despite seemingly adequate bladder drainage by CIC or an indwelling catheter.
- Maintenance of low intravesical pressure and avoidance of bladder overdistention is essential to successful CIC.
- The most common complications associated with catheter use include infectious (epididymitis, periurethral abscess, pyelonephritis), renal and bladder calculi, urethral stricture, and vesicoureteral reflux.
- The exact cause of upper tract deterioration in patients with long-term indwelling catheters is unclear; however, it is likely related to chronic “occult” or subclinical DO in the face of sphincteric dyssynergy providing a functional obstruction.
- Poor compliance is associated with vesicoureteral reflux, radiographic upper tract abnormalities, clinical pyelonephritis, and upper tract calculi.
- In patients with SCI, urodynamics should be performed after the initial neurologic injury is stable and whenever any significant changes in continence or voiding function occur. Periodic upper and lower tract evaluation using renal ultrasonography and cystoscopy should also be considered in all patients who require prolonged bladder management.
- CIC should be used cautiously in patients known to have autonomic dysreflexia.
- Intermittent catheterization may be performed by clean, aseptic, or sterile techniques.
- Any patient requiring intermittent catheterization may obtain up to 200 sterile catheters per month for one-time use.
- In most patients, catheterizations should be timed to maintain bladder volumes below the normal 400- to 500-mL capacity.
- Long-term indwelling catheters should be considered when anatomic, functional, or familial limitations prohibit performance of intermittent catheterization.
- In males, the benefits of an indwelling SPT over urethral catheterization include a lower incidence of epididymitis and urethral stricture disease with preservation of sexual function.
- The long-term risk for carcinoma in the patient with SCI with a chronic catheter has been estimated to be 8% to 10%. This association has not been identified in patients performing intermittent catheterization.
- The development of gross hematuria in patients with a chronic indwelling catheter should prompt further evaluation, including upper tract imaging, urine cytology, cystoscopy, and consideration of bladder biopsy.

If the guarding reflex arc is intact, this also may produce a striated sphincter contraction. The Credé maneuver is much easier in a patient with a lax, lean abdominal wall than in one with a taut or obese one, and it is more readily performed in a child than an adult.

A similar increase in intravesical pressure may be achieved by abdominal straining (Valsalva maneuver). The proper technique involves sitting and letting the abdomen protrude forward on the thighs. During straining in this position, hugging of the knees and legs may be advantageous to prevent any bulging of the abdomen. To increase intravesical pressure in this manner requires voluntary control of the abdominal wall and diaphragmatic muscles.

“Voiding” by the Credé or Valsalva maneuver is generally discouraged, because it is nonphysiologic and is resisted by the same forces that normally resist stress incontinence. Reflex sphincteric opening of the bladder outlet does not occur with external compression maneuvers of any kind, and, in many cases, an increase in outlet resistance may occur reflexively. If adequate emptying does not occur in the properly selected patient, other types of therapy to decrease outlet resistance may be considered; however, these treatments may adversely affect urinary continence.

The best chance for success with this mode of therapy (some would say it should never be used) is in the patient with an areflexic bladder and some degree of outlet denervation. This is most commonly seen in the patient with an autonomic neurogenic bladder (Lapides classification), T11 through L2 SCI in whom the sympathetic nervous supply is damaged, or after outlet resistance is decreased surgically or by botulinum toxin injection. Most of these patients already have stress incontinence, and the Credé or Valsalva maneuver simply helps the patient overcome outlet resistance to empty the bladder at a convenient time. These techniques also may be useful to decompress a neobladder when the outlet resistance is low either by volitional sphincteric relaxation or when surgically induced.

Vesicoureteral reflux is a relative contraindication to external compression or the Valsalva maneuver, especially in patients capable of generating a high intravesical pressure. The most flagrant misuse of this form of management is in the patient with a neurogenic bladder and poor detrusor compliance, because the increased storage pressures can cause upper tract deterioration with minimal filling. External compression or Valsalva maneuvers will only further aggravate this already dangerous situation.

Even when the patient has a flaccid bladder and/or low detrusor leak point pressures, close follow-up and periodic evaluation are necessary to avoid upper tract deterioration. Chang and colleagues (2000) reported the long-term urologic complications and residual volumes of 74 SCI patients with flaccid bladders who routinely performed the Credé maneuver as their primary form of bladder management for more than 20 years. Residual urine volume was greater than 100 mL in 93% of patients, and 50% were greater than 300 mL. The authors also reported that 59.5% developed ureteral dilation, 35.1% developed hydronephrosis, and 16.2% suffered renal deterioration. Males were significantly more likely to develop these complications than females, probably because of increased outlet resistance. Other complications included recurrent UTIs, pyuria, urinary lithiasis, epididymo-orchitis, genital-rectal prolapse, and hemorrhoids (Chang et al, 2000; Wyndaele, 2008).

Promotion or Initiation of Reflex Contractions

In patients with SCI and an intact sacral spinal cord, voiding can be elicited by exploiting existing spinal reflexes. The sacral micturition reflex occurs when tension receptors within the bladder wall are stimulated by bladder filling and activate sensory afferent neurons. Motor efferents from the spinal cord respond by generating a reflexive bladder contraction and, when of adequate magnitude, will result in voiding. Bladder contractions obtained in this manner are often involuntary and sporadic. In some cases, patients with SCI may be able to trigger this reflex voluntarily by manual stimulation of areas within the sacral or lumbar dermatomes. According to the classic reference by Glahn (1974), the most effective method of initiating a reflex contraction is rhythmic

suprapubic manual pressure (seven or eight pushes every 3 seconds). Quick repetitive stimulation in this manner is thought to produce a summation effect on the tension receptors in the bladder wall, resulting in activation of the bladder reflex arc. Ideally, the elicited contraction would be of sufficient magnitude and duration to empty the bladder. Other commonly used maneuvers to induce reflex detrusor contraction include pulling the skin or hair of the pubis, scrotum, or thigh; squeezing the clitoris; or digital rectal stimulation (Wein and Barrett, 1988). Patients able to void in such a way are encouraged to find their own optimal trigger points and position for urination. If induced emptying can be carried out frequently enough to keep bladder volume and pressure below the threshold for activation of the involuntary micturition reflex and below pressures that might cause upper tract deterioration, incontinence can be controlled, similar to timed voiding in normal individuals. Reflex voiding depends on the ability to stimulate detrusor contractions and may be most suitable for patients with SCI or conditions characterized by DO. To void reflexively, patients require manual dexterity and the ability to transfer to a commode, or at least the ability to use and maintain an external collecting device. For this reason, reflex voiding may not be suitable for many female patients. Surgical procedures to reduce outlet resistance should be considered if significant obstruction or sphincter dyssynergia are present. Complications with this voiding technique are most often related to the use of external collection devices or from the development of high-pressure storage resulting in upper tract deterioration. To ensure compliance, periodic surveillance should be performed with consideration of regular urodynamic evaluation.

Some clinicians believe that the micturition reflex can be “trained” by maintaining a copious fluid intake and periodically clamping an indwelling catheter or by CIC at regular intervals. This cyclic pattern of filling and emptying may promote storage, and emptying in a more physiologic manner focuses attention on the urinary tract and ensures an adequate fluid intake. It is true that balanced LUT function can be achieved while using this program (Opitz, 1984; Menon and Tan, 1992), but whether this is a cause-and-effect relationship is unknown and difficult to prove.

One fascinating set of experiments that relates to the concept of establishing or promoting a reflex pathway for micturition is that reported by Xiao and de Groat (1999). They created a reflex pathway from the skin to the central nervous system in cats by intradural microanastomosis of the left L7 ventral root to the S1 ventral root, leaving the L7 dorsal root intact to conduct cutaneous afferent signals. A detrusor contraction, without striated sphincter dyssynergia, could be initiated by scratching the skin or by percutaneous electrical stimulation in the L7 dermatome. The pathway was found to be mediated by cholinergic transmission at both ganglionic and peripheral levels. **The importance of this experimental model is that somatic motor axons were able to innervate parasympathetic bladder ganglion cells and therefore transfer somatic reflex activity to the LUT.** Xiao and colleagues (2003) reported on the first human clinical trial, in which 15 males with neurogenic overactivity and detrusor-external sphincter dyssynergia (DESD) secondary to complete suprasacral SCI underwent a ventral root microanastomosis between the L5 and the S2 and/or S3 ventral root. With a mean follow-up of 3 years, recovery in bladder storage and emptying function was reported in 10 (67%) patients. Average residual urine decreased from 332 mL to 31 mL, with resolution of UTIs and overflow incontinence. Postoperative urodynamics demonstrated the resolution of DO and DESD to near-normal storage pressures, with synergic voiding and without DESD. Improvement in bowel function also was noted. Xiao and colleagues (2005) subsequently reported on 20 children with neurogenic bladder from spina bifida, among whom 17 of 20 (71.4%) demonstrated urodynamic improvements after surgery. Partial loss of L4 or L5 motor function, ranging from slight muscular weakness to visible foot drop, was reported in 5 of 20 patients. Xiao (2006) recently reviewed the initial human trials to date, and although encouraging results have been reported, experiences from other centers are needed to confirm these findings.

Stimulated Myoplasty for Bladder Emptying

Few treatment options are available for patients with detrusor underactivity except for self-intermittent catheterization. Restoration of bladder contractility remains an elusive goal for most patients with this condition. The first animal feasibility studies to augment bladder contractility used a unilateral rectus abdominis muscle wrap over the bladder to facilitate bladder emptying (Chancellor et al, 1994a). The rectus muscle, with intact neurovascular pedicle, was dissected free at one end and wrapped over the bladder, where it was reattached to itself and created a spherical configuration housing the bladder. Evaluation of the transposed muscle showed no damage to the blood supply or innervation of the rectus muscle, and the underlying bladder retained its volume despite neurogenically induced underactivity. This model was touted as the precursor for a clinical trial wherein the patient would learn to contract his rectus muscle voluntarily and create sufficient extrinsic pressure to void. The first case report using the rectus myoplasty involved a 33-year-old man with an L4 SCI from a gunshot wound 10 years before enterocystoplasty covered by the left rectus muscle transposed over the bladder (Chancellor et al, 1994b). One month later the patient could void by contracting his rectus muscle generating 50 cm H₂O detrusor pressure as recorded by video-urodynamic testing. This ability persisted for 11 months until the case was reported in the literature. Initial experience with the rectus abdominis was limited to this single case despite the relative ease of the technique when compared to the complexity of the latissimus dorsi free flap requiring neurovascular reanastomosis. Latissimus dorsi cardiomyoplasty was being used for heart failure in selective cases during this period (Blanc et al, 1993), and the concept for a similar application for detrusor underactivity was embraced by groups in San Francisco and Germany. Von Heyden and associates (1998) experimented with dogs and pigs using the rectus muscle with its segmental intercostal nerve innervation and they abandoned the muscle because of the lack of suitable motor nerves for muscular control of the flap. Free latissimus dorsi muscle flaps were harvested and transferred over the bladder in dogs; revascularization and electrical stimulation of the thoracodorsal nerve successfully induced pressures sufficient for partial evacuation of the bladder. The advantage of a singular nerve supply with ample geometry provided by the latissimus dorsi free flap led to the first clinical application in 1998 by Stenzl and colleagues (1998). Three patients with bladder acontractility, dependent on catheterization, were treated with latissimus dorsi myoplasty and all three were able to void by abdominal straining and avoid catheterization. A larger clinical study followed using the free transfer of the latissimus dorsi muscle to restore voluntary voiding, with 14 of 20 patients able to void spontaneously with postvoid residual volumes of less than 100 mL (Ninkovic et al, 2003). The largest latissimus dorsi detrusor myoplasty experience was reported by Gakis and colleagues (2011) in 24 patients with detrusor underactivity and a mean follow-up of 46 months. Preoperatively, all patients required intermittent catheterization 4 to 7 times daily. This multi-institutional study from 2001 to 2008 resulted in complete voluntary voiding in 71% of patients with a 91% reduction in UTIs. Three patients reduced the frequency of catheterization by 50%, and 4 patients failed to show improvement.

ADDITIONAL THERAPIES FOR STORAGE AND EMPTYING FAILURE: CIRCUMVENTING THE PROBLEM

Patients with urinary incontinence may choose to wear an external collecting device or absorbent pad to manage leakage. For some, their incontinence is minimal or they are unwilling or unable to undergo more definitive treatment. However, in some instances, patients have failed multiple anti-incontinence procedures and external collecting devices or pads are the only management options available.

KEY POINTS: ADDITIONAL THERAPIES FOR EMPTYING—INCREASING INTRAVESICAL PRESSURE OR FACILITATING BLADDER CONTRACTILITY

- The Credé maneuver is most effective in patients with decreased bladder tone who can generate an intravesical pressure greater than 50 cm H₂O and have decreased bladder outlet resistance.
- Both the Credé and Valsalva maneuvers may elevate intravesical pressure sufficiently to cause upper tract deterioration, especially if performed in the setting of poor detrusor compliance. Even when the patient has a flaccid bladder and/or low detrusor leak point pressures, close follow-up and periodic evaluation are warranted.
- In patients with SCI with an intact sacral spinal cord, reflex voiding can be initiated through activation of the sacral micturition reflex. Voiding can be elicited by rhythmic suprapubic manual pressure; pulling the skin or hair of the pubis, scrotum, or thigh; squeezing the clitoris; or digital rectal stimulation.
- Reflex voiding depends on the ability to stimulate detrusor contractions and may be most suitable for patients with SCI or conditions characterized by neurogenic DO.
- Stimulated myoplasty for bladder emptying failure has been accomplished, but requires further investigation.

External Collecting Devices

To date no external urinary collecting device for females has been successful or effective. The female urethral meatal anatomy has made it difficult to design a leak-proof apparatus that is easy to apply and maintain. However, external collecting devices for men—the condom catheter, penile sheath, or Texas catheter—are generally effective in urine collection. For male patients who are unable to perform CIC because of cognitive impairment, quadriplegia, or lack of reliable assistance from a caregiver, the condom catheter may be preferable over an indwelling urethral catheter. A study by Saint and colleagues (2006) reported the results of a randomized controlled trial of 75 hospitalized male veterans in which 41 men were randomized to wear an indwelling urethral catheter and 34 men wore a condom catheter. The median hospital stay was 3 days. Condom catheters were associated with a lower incidence of bacteriuria, symptomatic UTIs, and death compared to the use of an indwelling urethral catheter. Patients also reported that external urinary collection devices were more comfortable and less restrictive on daily activities than indwelling catheters. It should be emphasized that despite the reduced incidence of adverse outcomes, the use of external collection devices and absorbent products is associated with a higher risk for UTIs compared with cases in which no appliances are used (Sturmann et al, 1989). It is generally recommended that condom catheters be changed daily, because the risk for UTI is increased when catheters are changed less frequently (Waites et al, 1993; Zimakoff et al, 1996). The use of a condom catheter is not free of complications. It can cause allergic reactions, skin maceration, and/or penile edema. Furthermore, the penile skin and glans should be examined at every catheter change to ensure no skin breakdown or contact reactions have occurred (Newman, 1999). These devices have the potential to cause pressure necrosis of the penis and, when severe, may even damage the urethra (Golji, 1981). Pressure-related complications are more likely to occur in patients with impaired sensation, such as those with neurogenic LUT dysfunction (Golji, 1981). External urine collecting devices also are prone to dislodge or fall off, especially if the patient is wearing an inappropriate size. Additionally, patients with SCI may have reflex penile retraction and paralysis associated with pelvic bending, making it difficult to maintain the device. Van Arsdalen and colleagues (1981) reported on the

use of a noninflatable penile prosthesis in this type of patient to facilitate applying and maintaining a condom catheter. Zermann and associates (2006) describe the long-term results of penile prosthetic surgery for urinary incontinence and/or erectile dysfunction in neurologically impaired patients. At a mean follow-up of 7.2 years, 90.3% of urinary management problems were resolved. The overall infection rate was 5%, and the rate of explantation was 7.7%, which is comparable to the explantation rate in non-neurogenic patients.

Absorbent Products

Urinary incontinence can be a socially debilitating problem leading to fear of odor, discovery, and embarrassment. Many patients with urinary incontinence purchase and wear some type of absorbent product, which may include pads, shields, drip collectors, guards, undergarments, briefs, diapers, or underpads. Consumers spend billions of dollars on these products (Getliffe et al, 2007; Erikson et al, 2008) and for the majority, selection is often based on trial and error, cost, convenience, and manufacturers' claims (Baker and Norton, 1996; Fantl et al, 1996). Recently, the National Association for Continence (NAFC) formed a Council of experts with the goal of establishing national, independent quality performance standards for disposable adult absorbent products. The full recommendations of the NAFC Council include nine performance assessment parameters: "rewet rate (a measure of a product's ability to withstand multiple incontinent episodes between changes), rate of acquisition (a measure of the speed at which urine is drawn away from the skin by a product), product retention capacity (a measure of a product's capacity to hold fluid without rewetting the skin), sizing options, absorbency levels, product safety, closure technology, breathable zones (a measure of the air permeability across a textile-like fabric at a controlled differential pressure), and elasticity" (Muller and McInnis, 2013). More research is needed to evaluate the impact of these parameters on cost and quality of care.

Often recognized as the authority in the management of the incontinent patient, urologists should acknowledge the basic nursing principles and skin care recommendations that may significantly contribute to patient care. Absorbent products should be changed frequently to help avoid buildup of odor and limit the exposure of the skin to urine. Prolonged exposure of the skin to a wet environment may lead to supersaturation and disruption of the skin's protective barriers, promoting skin maceration, dermatitis, and possibly infection. **Incontinence-associated dermatitis (IAD) can be defined as inflammation of the surface of the skin with redness, edema, and, in some cases, bullae containing clear exudate (Gray et al, 2007). IAD predominately occurs in skin folds and may promote candidiasis or bacterial skin infections. Gray and associates (2007) published an excellent review of the epidemiology, pathophysiology, and management of IAD with recommendations for prevention and treatment.**

Further information regarding the types of absorbent products available for males and females, including a review of skin care management, external collection, and urethral compression devices

can be found in the book by Newman and Wein (2009) and the comprehensive resource guide available from the NAFC (2008) (<http://www.nafc.org>).

KEY POINTS: CIRCUMVENTING THE PROBLEM

- No reliable external urine collecting device exists for females; however, these devices, or condom catheters, can be used successfully in men who are unable to perform CIC.
- Condom catheter use is associated with a lower incidence of bacteriuria, symptomatic UTIs, and death compared to the use of an indwelling urethral catheter. They are also perceived to be more comfortable and less restrictive on daily activities than indwelling catheters.
- Pressure-related complications from condom catheter use are more likely to occur in patients with impaired sensation or cognition.
- IAD can be defined as inflammation of the surface of the skin with redness, edema, and, in some cases, bullae containing clear exudate. IAD predominately occurs in skin folds and may promote candidiasis or bacterial skin infections.

SUMMARY

Disorders of the storage and emptying phases of micturition have various causes and can be classified by the location of the dysfunction, either at the bladder level or the bladder outlet. Treatment strategies are numerous and often combine medical and surgical management. Continued research is warranted to further our understanding of the pathophysiology of storage and emptying failure so we may continue to improve patients' quality of life.

Biology and Principles of Aging

Demographics of Aging

Clinical Evaluation of the Geriatric Urology Patient

Major Geriatric Syndromes and Urology

End-of-Life Care and Urology

Summary

Aging is a universal process that affects all living organisms. Alterations in anatomy and physiology associated with the normal aging process lead to functional changes in all aspects of human medicine including the genitourinary system. This chapter will focus on human aging and the associated alterations in structure and function that affect urologic care for older adults.

Dr. Ignatz Leo Nacher was the first to use *geriatrics* as a clinical term in a scientific publication (Nacher, 1909). That article highlighted early concepts about considering care for older adults as a distinct branch of medicine. More than a century later, geriatrics is not only a recognized and respected distinct specialty within general medicine, but in multiple other health care disciplines including nursing, pharmacy, physical and occupational therapy, social work, and others. More recently, the growing need for geriatrics expertise in all of the medical and surgical specialties including urology has been recognized (Drach and Griebling, 2003; Bell et al, 2011). Research efforts and educational materials have been developed and have helped to expand knowledge about the unique aspects of medical needs and care delivery for older adults with urologic health problems (Webb and Duthie, 2008; Griebling, 2009b; Guzzo et al, 2013; Griebling, 2014; Reuben et al, 2014).

In clinical medicine, the term *geriatrics* is most commonly used to refer to care of patients 65 years of age or older. In part, this is a social construct because this is the age when Medicare and Social Security benefits have traditionally started for people in the United States. The World Health Organization (WHO) actually classifies people older than age 60 as being “elderly,” because life expectancy is still shorter in many parts of the developing world. With continuing advances in medical care and extended longevity in many developed countries, many would argue that clinical geriatrics now encompasses an even older population, often focused on those 70 years and older. However, in many circumstances, **chronologic age may be a much less important factor than physiologic or functional age.**

One of the basic principles in geriatric medicine is a focus on **patient-centered care**. This places the goals of care for patients, their caregivers, and other loved ones at the core of clinical evaluation and treatment. In some cases the goal may be treatment with curative intent. However, in many instances this may not be possible. In all cases there should be an **emphasis on quality of life (QoL), and stabilization or improvement in functional status.** This frequently includes a goal to maintain independence for as long as possible and to reduce the need for assistance or care from others to the extent possible. Promotion of urinary continence and improved bladder function is a good example of this type of care within the scope of urologic practice. Improvement in independent

toileting and continence status can reduce the need for caregiver assistance and may in turn decrease the risk of need for nursing home placement (Andel et al, 2007).

BIOLOGY AND PRINCIPLES OF AGING

There are several plausible theories about why people age and experience changes over time. The **Hayflick limit** describes the phenomenon of limitations in the number of cellular replication cycles inherent to most cell types (Hayflick and Moorhead, 1961). This may result from a variety of factors. **Telomere shortening** has been identified as a common cellular change seen with aging. **Activation of various tumor suppressor genes** or other genetic pathways may also serve to either promote or suppress cellular senescence. **Release of free radicals and other types of oxidative stress increase** with aging and can lead to mitochondrial damage and other intracellular changes. Some cell types exhibit **apoptosis or programmed cell death**. Numerous inflammatory biomarkers have been shown to increase with age and could potentially accelerate the aging process. **These accumulated changes can lead to the alterations in tissue and organ function commonly seen with advancing age.** These types of changes can influence clinical outcomes including tissue and wound healing, restoration of function, and outcomes of reconstructive urologic surgical procedures (Griebling, 2009a).

Physiologic Aging

Changes in function with increasing age can be seen in essentially all organ systems. Generalized changes can be exacerbated by specific disease progression. A number of these different processes have direct impact on genitourinary health, urologic function, and clinical decision making relative to urologic care.

Renal blood flow decreases with aging. This can be caused by atherosclerotic plaque formation in the renal arteries and other vascular diseases. Kidney mass also decreases progressively after 65 years of age. This leads to a **concomitant decrease in the glomerular filtration rate (GFR) of approximately 10 mL/min per decade**, reaching about 50% by age 80. Approximately 26% of all adults older than age 70 have some degree of chronic renal impairment. **This can have substantial impact on dosage of medications cleared by renal metabolism** (Hanlon et al, 2009). In many cases, lower doses will be adequate to achieve clinical effects, and doses typically used in younger patients may lead to toxicity or untoward side effects. Renal concentrating ability is also reduced, and older adults tend to make a larger volume of more dilute urine (Sands, 2003).

Accurate estimation of renal function in older adults can be challenging. **Serum creatinine levels alone may not reflect actual renal function**, particularly in frail older adults or those with reduced lean body mass. In these patients, serum creatinine measurements will tend to overestimate function and underestimate the degree of renal impairment (Giannelli et al, 2007). Measures that calculate estimated GFRs including the Cockcroft-Gault equation will tend to be more accurate in this elderly population (Scrutinio et al, 2009). Routine assessment and reporting of estimated GFR can help to improve prescribing accuracy for drugs that require renal metabolism (Kurtal et al, 2009).

The diurnal pattern of water consumption and urine production also changes with aging. Total water intake appears to decrease among older adults with aging, with population studies indicating that only 19% to 27% of geriatric patients actually reach the daily recommended levels of fluid consumption (Zizza et al, 2009). Endogenous secretion of arginine vasopressin decreases with age. Because of this, older adults tend to excrete the majority of their fluid output at night, which can lead to symptomatic nocturia (Tani et al, 2008). This relative nocturnal polyuria can be a major contributing factor to clinically bothersome symptoms (Natsume et al, 2009).

Cardiac compliance and elasticity decrease with aging, which leads to decreased cardiac output and stroke volume. This can have important implications, particularly when considering older adults as candidates for urologic surgery. Hypertension is also a common condition seen with aging and can negatively influence functional reserve capacity. Hypertension in older adults can be caused by myriad factors, including renovascular conditions.

The **respiratory system** undergoes substantial changes with aging. Pulmonary surface area for oxygen diffusion decreases, leading to changes in ventilation-perfusion ratio. Chest wall elasticity and respiratory muscle strength both decrease, and there is decreased maximal expansion. Pulmonary fibrosis and chronic obstructive pulmonary disease (COPD) are common conditions seen with aging and can also negatively influence respiratory function. Cigarette smoking increases these risks and exacerbates age-related changes. Increased cough may worsen symptoms among patients with concomitant stress urinary incontinence (UI). As with cardiovascular disease, alterations in pulmonary function play a major role in consideration for surgical therapy in older adults. **Although most deaths in the perioperative period in geriatric patients are caused by cardiovascular events** such as myocardial infarction and stroke, **most prolonged hospitalizations are the result of pulmonary problems** such as pulmonary embolism, pneumonia, and respiratory failure and difficulty weaning from ventilator support (Somme et al, 2003).

Hepatic function also declines with time. Loss of hepatocytes leads to **decreased metabolic efficiency for drugs cleared by hepatic metabolism**. Alterations in the cytochrome P450 mechanism are common and can be influenced by a variety of medications. This can alter hepatic metabolism and may necessitate dose adjustment of medications cleared by the liver. It is also important to consider drug-drug interactions that may be influenced by changes in the cytochrome P450 pathway. Certain foods, particularly grapefruit, can also interfere with the cytochrome P450 pathway and potentially impair drug metabolism.

Immunologic function, particularly T cell-mediated immunity, tends to slowly decline with age. This leads to a generalized increase in the risk of infections among older adults including a greater risk for both upper and lower urinary tract infections (UTIs) and pneumonia.

Gastroenterologic changes include a generalized slowing of bowel motility, which can lead to alterations in stool frequency and consistency. **Altered water reabsorption from the colon can increase risk for constipation**. This can be particularly affected by anticholinergic and other medications that may slow bowel motility. This in turn increases the risk for constipation and fecal impaction with aging. These conditions can be exacerbated by medications used in the treatment of some urologic conditions such as antimuscarinics prescribed for overactive bladder (OAB), urinary urgency and frequency, and urgency UI (Kim et al, 2014b).

Vascular changes are common with aging. These include changes in peripheral vasculature, cardiac and central nervous system vascular anatomy, and renal perfusion. Hypertension, tobacco use, and diabetes all contribute to vascular disorders seen more commonly with aging. Plaque formation and atherosclerotic disease may limit circulation to the kidneys, bladder, penis, and other genitourinary organs. Decreased penile blood flow can lead to erectile dysfunction in elderly men (Justo et al, 2010). Pelvic ischemia has also been linked to the subsequent development of lower urinary tract symptoms (LUTS) in older adults (Pinggera et al, 2008; Kim et al, 2010a). Color Doppler ultrasound demonstrates diminished arterial blood flow, which is associated with pelvic ischemia and higher rates of LUTS. Animal models show that pelvic ischemia is associated with increased levels of proinflammatory cytokines and other biomarkers suggesting that oxidative stress plays a role in this process (Nomiya et al, 2012). Free radical release and oxidative stress may cause ultrastructural damage that can lead to neurodegeneration and other anatomic and functional abnormalities (Azadzo et al, 2007, 2010, 2011; Tyagi et al, 2014b). Early research suggests that melatonin and other compounds such as free radical scavengers could be potential agents to prevent urologic sequelae from this type of ischemia (Nomiya et al, 2013).

Metabolic changes are common with aging. Rates of both the metabolic syndrome and type 2 diabetes mellitus increase substantially with advancing age. These conditions can contribute to multiple clinical conditions including vascular insufficiency, erectile dysfunction, renal impairment, and bladder dysfunction (Park et al, 2008). With aging, there is a **relative increase in adipose tissue and a loss of lean body mass and muscle**. This influences fluid distribution and drug metabolism and increases the rate of accumulation of lipophilic metabolites. **Because of this, many lipophilic drugs need to be dose titrated in older adults**. Obesity and overweight have reached epidemic proportions in the United States and are associated with increased rates of associated medical conditions including diabetes and metabolic syndrome.

Aging and the Lower Urinary System

Many of the common genitourinary conditions occur with higher incidence and prevalence rates in older adults, but these should not necessarily be considered a normal or inevitable part of the aging process. Examples include UTIs, UI, erectile and sexual dysfunction, and many of the urologic malignancies. Various changes commonly occur in the genitourinary tract as a result of the normal aging process. One of the greatest challenges in geriatric urology is to differentiate between normal aging and pathologic processes that can affect the genitourinary system and lead to associated symptoms.

Several structural changes that occur in the bladder with aging have been linked to functional changes that can cause specific clinical symptoms (DuBeau, 2006). The ratio of smooth muscle to collagen in the wall of the bladder decreases, which may lead to decreased contractile strength. Studies using electron microscopy and other structural imaging modalities have demonstrated these changes as well as development of "dense bands" and loss of caveolae (Elbadawi et al, 1993; Lowalekar et al, 2012). These alterations have been linked to increased involuntary detrusor contractions and changes in contraction strength and velocity. Functional bladder innervation also appears to diminish over time with chronic obstruction or overactivity (Fry et al, 2011). Changes in detrusor anatomy can also lead to a decrease in elasticity and compliance, defined as the change in bladder volume related to bladder pressure. These alterations can lead to changes in both urine storage and bladder emptying (Elbadawi et al, 1997). Sensory changes may be caused by alterations in the epithelium and associated receptors and neurotransmitters. Oxidative stress damage may also occur as a result of the aging process and may be associated with symptomatic bladder dysfunction (Aybek et al, 2011). Bladder capacity tends to remain relatively stable or to decrease only slightly with advancing age (Pfisterer et al, 2006a, 2006b).

Progressive anatomic changes in pelvic floor support and muscle strength can also occur with aging. Cadaveric studies using biopsy

specimens of the urogenital diaphragm have documented that striated muscle tissue is substantially reduced or absent in many older women relative to connective tissue (Betschart et al, 2008). However, aging may not be the sole risk factor, and other variables including parity and history of vaginal delivery should be considered (Weemhoff et al, 2010). Bony structural support in the pelvis may also contribute to these changes and can potentially be influenced by geriatric skeletal disorders such as osteopenia or osteoporosis (Richter et al, 2013). Pelvic floor muscle dysfunction is common among elderly women, and research indicates many of them may not be able to generate voluntary muscle contractions on initial examination (Talaszy et al, 2012). Some of this observed change in pelvic floor support may be a result of apoptotic cellular changes in these tissues (Saatli et al, 2014).

Decreased striated muscle density in the rhabdosphincter can lead to an increased propensity for stress UI, particularly in elderly women. These anatomic changes may be caused, at least in part, by apoptosis associated with aging (Strasser et al, 1999, 2000). This can subsequently lead to a loss of the normal circumferential anatomy and appropriate urethral resistance and closure pressures (Klauser et al, 2004; Kurihara et al, 2004).

DEMOGRAPHICS OF AGING

Aging and Population Trends

The overall population of the United States and of many other developed countries is aging at a very rapid pace. This is the result of a number of factors including improved longevity, decreased overall birth rates, and enhanced medical technology that makes effective treatment for many conditions possible. Older adults, defined as those 65 years of age and older, currently account for approximately 13% of the total U.S. population. However, it is estimated that this will increase to at least 20% by the year 2030 (Fig. 88-1). The fact of the matter is that those older than age 85 represent the fastest growing segment of the U.S. population. The aging of the “baby boom” generation including those born between 1946 and 1964 is also contributing to this demographic trend. Approximately 10,000 people per day now turn 65 years of age in the United States. This is a global phenomenon and is occurring in almost all portions of the world with the exception of sub-Saharan Africa, where mean life expectancy is still relatively shorter. Worldwide, approximately 420 million people were older than age 65 in 2000, and it is estimated that this will increase to more than 973 million by 2030 (Centers for Disease Control and Prevention [CDC], 2014). Remaining life expectancy for those already age 65 continues to steadily increase in the United States and in many developed countries worldwide.

The vast majority of older adults continue to live in the community, with only a minority requiring residential long-term care in nursing homes or other types of facilities. The need for nursing home services does increase with advancing age, with approximately 15% of those older than 85 years living in long-term care facilities. (Federal Interagency Forum on Aging-Related Statistics, 2012).

Global Implications for Urologic Health Care

As the population ages, there will be an increased need for health care providers with specific knowledge and skills to evaluate and treat clinical conditions in this heterogeneous and complex patient population. In many ways, urology is by its very nature a geriatric specialty. Except for those who exclusively practice pediatric or adolescent urology, most urologists in general practice have a majority of patients in their practice who are older than 65 years. Urology consistently ranks among the top three specialties in the United States in terms of the total volume of older adults seen in clinical practice. Only ophthalmology and cardiology outrank urology in terms of the total volume of geriatric care provided in the specialty (Drach and Griebing, 2003).

Epidemiologic studies have consistently shown that incidence and prevalence rates for the most common urologic conditions

tend to increase substantially with advancing age. This includes UI and lower urinary tract dysfunction, pelvic organ prolapse (POP), UTI, bladder outlet obstruction (BOO), and benign prostatic hyperplasia (BPH). With the exception of testicular cancers, all of the urologic malignancies have a predilection to occur in older adults. Sexual health problems are more common among older men and women compared with younger patients. **Increased population growth among older adults will mean that more elderly patients will develop urologic disorders**, which in turn will likely translate into increased rates of surgical care among geriatric patients (Takao et al, 2008). All these factors contribute to the expanding need for expertise in geriatric urology (Drach and Griebing, 2003).

CLINICAL EVALUATION OF THE GERIATRIC UROLOGY PATIENT

Older adults frequently have more complex health needs compared with younger patients. This is in part because of changes associated with aging, and also the increase in comorbidity seen in elderly patients. **Physiologic alterations associated with aging can lead to loss of functional reserve capacity**, which in turn leads to impaired response to stressors such as infection, surgery, chemotherapy or other urologic conditions or treatments (Fig. 88-2). The concept of the body trying to restore or remain in balance in response to internal or external stressors has been termed *homeostasis*. In geriatrics, the decline in functional reserve capacity associated with aging is sometimes described using the term *homeostenosis*, a reference to the narrowing of arteries that occurs with atherosclerosis. For a given stressor, older adults with lower baseline functional reserve capacity may not be able to respond as well or may actually have a more exaggerated response compared with younger patients with more reserve. An example would be the development and progression of postoperative pneumonia. In a healthier younger patient, this may be relatively indolent and self-limited and may promptly resolve with appropriate antibiotic therapy. However, in a more debilitated older adult with less functional reserve capacity, the same level of pneumonia could result in a much more profound illness that could require more intense treatment and time to resolve. It could also have a higher likelihood of progression to more serious disease.

One of the most commonly used measures of comorbidity is the **Charlson Comorbidity Index (CCI)**. This was initially developed to identify underlying disease conditions that could help to predict subsequent mortality risk (Charlson et al, 1987). The instrument assigns points to each chronic condition, with a sum score indicating level of risk based on comorbidity. The CCI has been used extensively and has been validated for use in surgical patients. It has been applied recently to some urologic conditions such as kidney cancer to help make clinical decisions between surveillance and surgery in elderly patients (O'Connor et al, 2009). Self-reported health is an important predictive factor among geriatric patients. **Poor self-reported health among older adults has been linked to increased overall and disease-specific mortality and has in some cases been found to be a stronger negative predictor than physician-rated health status** (Giltay et al, 2012).

Because of this, older adults often require more involved clinical evaluation in relation to their urologic treatment. This includes a number of specific areas that are somewhat unique to geriatrics but that influence overall care for the patient. Development of comorbid chronic health conditions is common with aging. **The majority of adults older than 65 years have at least one chronic medical condition, and more than 50% have at least two** (Wolff et al, 2002).

Functional Assessment

Functional assessment in geriatrics includes a number of components designed to evaluate reserve capacity and levels of dependence or independence. This includes evaluation of an older adult's ability to independently perform specific tasks. **A clear understanding of an individual patient's baseline functional status is vital to his**

Figure 88-1. Age-sex population pyramids based on U.S. census data. A, 1950 census. B, 1990 census.

or her care (Dunlop et al, 2002). This provides a framework to better understand subsequent changes associated with surgery or other treatments. **Baseline functional status has been shown to be predictive of other health care outcomes** including remaining life expectancy, morbidity, and mortality (Lubitz et al, 2003). There is wide heterogeneity among older adults, and this is not specifically related to chronologic age. Progression of clinical disorders and response to treatments can both lead to changes in functional status, and the clinician needs to be able to identify these alterations compared with baseline function. The following components form the basic parts of functional assessment in geriatric patients.

Activities of Daily Living

The **activities of daily living (ADLs)** include basic tasks people need to do to function and interact in the world. These include bathing, dressing, grooming, using the toilet, feeding, and perform-

ing physical ambulation. Each of these factors is evaluated on a scale ranging from complete independence to needing full assistance (Lawton and Brody, 1969). Alterations in ADLs are among the most predictive factors for need of caregiving assistance with aging. Although there can be variations in the pattern of progressive need for help with ADLs, bathing is typically the one for which people first need assistance. Feeding tends to be preserved the longest, even in people who are otherwise quite debilitated. A simple way to determine if people are beginning to need assistance with their ADLs is to ask if someone is able to shower or bathe independently. This can be an early sign of alterations in overall status that may be predictive of future change.

Instrumental Activities of Daily Living

The **instrumental activities of daily living (IADLs)** add a higher cognitive and executive function component to the basic ADLs.

Figure 88-1, cont'd C, 2010 census. D, 2030 (projected). Note the sizeable increase in total population and the progressive change over time from a pyramid shape, in which the majority of the total population is relatively young, to a rectangular shape, in which a substantially larger portion of the population is older than 65 years. The pronounced bulge in the graphs for 1990 and 2010 represents the “baby boom” generation. (From U.S. Census Bureau, www.census.gov.)

These include shopping, preparing food, performing housekeeping tasks, doing laundry, managing finances, using the telephone or other communication devices, managing medications, and using transportation. As people age, it is common for them to need some assistance with the IADLs before they need help with ADLs, although there can be quite a bit of variation in these change patterns. Many community and home-based services are available to help with both ADL and IADL needs as people age.

Both ADL and IADL function can be predictive of overall health status and future health variables. Using data from the Medicare Current Beneficiary Survey from 1992 to 1998, Lubitz and colleagues examined nearly 17,000 people aged 70 at the time of enrollment and studied longitudinal outcomes stratified by functional status (Lubitz et al, 2003). Those who were independent in all ADL and IADL variables had an estimated remaining life

expectancy of 14.3 years and annual health care costs of \$4600 (in 1998 dollars). Loss of independence in one IADL reduced expected remaining life expectancy to 12.4 years and increased annual health care expenditures to \$8500. Needing assistance with at least one of the basic ADLs led to a reduction of remaining life expectancy to 11.6 years and increased annual health care expenditures to \$14,000. These data clearly demonstrate that loss of functional independence is linked to reduced life expectancy and increased health care costs. Understanding baseline ADL and IADL function also helps clinicians to monitor changes in status over time and with treatments.

Mobility

Limitations in mobility can have a substantial impact on overall functional status for older adults. **Mobility impairment is**

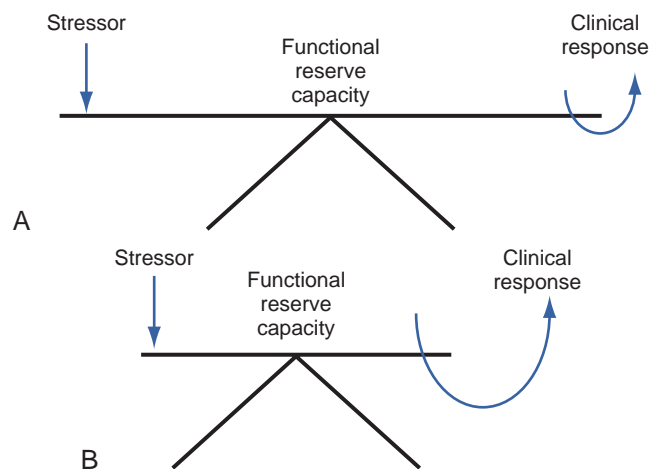

Figure 88-2. Changes in functional reserve capacity with aging. With aging, there is a progressive decline in functional reserve capacity. This diagram demonstrates the conceptual model of *homeostasis* (A) wherein the body tries to maintain balance in response to various stressors such as disease or clinical treatment. Progression to *homeostenosis* (B) is caused by relative decline in functional reserve capacity. In this case, response to identical stressors may be more difficult or complications more pronounced owing to loss of functional reserve capacity.

frequently associated with urologic issues including the development of what is termed *functional incontinence*. In these patients, UI is a result of factors other than those related to the bladder, such as impaired mobility or cognition. Improvement in the underlying factors such as return of independent mobility could help to improve or resolve the UI.

One of the most commonly used and well validated clinical assessments for mobility is the **Timed Up and Go (TUG) test** (Podsiadlo and Richardson, 1991). To perform this test, the patient is seated in a stationary, hard-backed chair with arms. He or she is asked to stand, walk 3 meters, turn, return to the chair, and sit down. If the patient normally uses an assistive device such as a walker or cane for ambulation, he or she is allowed to use it during the test. Most older adults without mobility limitations can complete this task in 10 seconds or less. Frailer older adults who still maintain good mobility independence can complete this in 20 seconds or less. Inability to complete the test or needing more than 20 seconds to do so indicates a higher level of dependence for mobility. Although it seems quite simple, the TUG test measures a number of complex components associated with independent mobility. These include the ability to follow directions, quadriceps strength in standing from the seated position, gait, balance, and coordination. Diminished quadriceps strength is recognized as an early sign of decreased overall muscle function.

One of the newer conceptual models that expands on the complexity of the concept of mobility is the **Life Space Assessment** (Baker et al, 2003). This examines the degree to which a person is able to independently interact with his or her world. Measurements range from the extremes of being confined to one's bedroom to being fully able to travel and go out independently into the greater community and world at large. This can have important implications for urologic function. For example, someone who is limited to his or her bedroom may require complete assistance for toileting. An understanding of baseline life space capabilities also helps to better evaluate postoperative function in people undergoing surgery (Stewart et al, 2009).

Slower gait speed in elderly patients has been closely linked to reductions in remaining life expectancy, chronic disability, nursing home placement, and injurious falls (Hardy et al, 2007; Rothman et al, 2008). It has been shown to be one of the strongest predictors of mortality and other negative health outcomes among older

adults (Seino et al, 2013). It is likely that this represents a marker condition that includes changes in other functional status components including muscle strength and sarcopenia, nutritional status, and baseline levels of activity. Fatigue and easy exhaustion with physical activity are also associated with increased risk of mortality in elderly patients (Hardy and Studenski, 2008). These factors, including diminished levels of physical activity, a sense of easy exhaustion, and reduced gait speed, are all clinical components of the frailty phenotype (Fried et al, 2001).

Cognition

Cognitive changes in older adults are quite common and can be acute or chronic. An appreciation of baseline cognitive status for an individual patient is important, particularly in relation to changes that can be observed longitudinally over time or directly related to various therapies. Alterations in cognitive status may be associated with delirium or dementia, and recognition of these factors is important for correct diagnosis and subsequent treatment.

Various methods can be used to assess cognitive status. The most commonly used validated instruments include the **Folstein Mini-Mental State Examination (MMSE)** and the **Mini-Cog** (Folstein et al, 1975; Borson et al, 2000). Both instruments provide valuable information on the cognitive status of patients. The MMSE provides a brief cognitive assessment in several domains including orientation, ability to follow directions, visual-spatial capacity, and short-term memory. It can be influenced by educational status, with more highly educated individuals tending to score higher at baseline. The instrument is graded on a scale from 0 to 30, with scores of 24 or lower generally considered positive for dementia.

The Mini-Cog assesses ability to follow directions, visual-spatial cognition, and short-term memory and executive function. It is less influenced by educational level than the MMSE. Advantages of the Mini-Cog include ease of administration and shorter time required to complete assessment. It can usually be done within about 3 minutes and includes two components: a three-item short term repetition with recall, and a clock-drawing test. Subjects are asked to repeat and remember three words. These should be unrelated items and should not include abstract ideas, emotions, colors, or terms that modify or describe one another. Examples of words often used in testing are *apple*, *penny*, and *table*. These are also somewhat more complex because they all have two syllables. After the patient attempts to repeat the words, he or she is asked to draw the face of a clock including all 12 numbers, and to set the hands to a specified time (usually 11 : 10). The patient may be provided with a paper that already includes the circle, or he or she may draw the circle and complete the clock (Fig. 88-3). After the patient has finished drawing the clock, he or she is asked to repeat the three previously presented and repeated words. This concludes the test. Zero to three points are assigned for short-term recall, one for each correctly repeated word. Either zero or two points are assigned for the clock drawing, depending on whether all components were correctly completed. A total score of 0 to 2 is positive for possible dementia, and a score of 3 to 5 is considered negative. The Mini-Cog has been validated in a variety of settings, does not require specialized equipment, is relatively quick and easy to administer, and is less influenced by language and educational status than are other available tests.

Understanding preoperative cognitive function is important for several reasons. It can help gauge the capacity of patients to provide informed consent for treatment and can serve as a comparison for later observed cognitive status. **Advance directives and informed decision making regarding health care are important parts of geriatric practice.** Reduced baseline cognitive function has been associated with worse postoperative outcomes in elderly surgical patients. Examples include a higher incidence of delirium (78% vs. 37%, $P < .001$), longer hospital stays (15 ± 14 vs. 9 ± 9 days, $P = .008$), higher rate of discharge institutionalization (42% vs. 18%; $P = .001$), and higher 6-month mortality (13% vs. 5%; $P = .040$) (Robinson et al, 2012).

Potentially reversible causes of memory loss in patients should be considered and addressed if appropriate. Conditions commonly

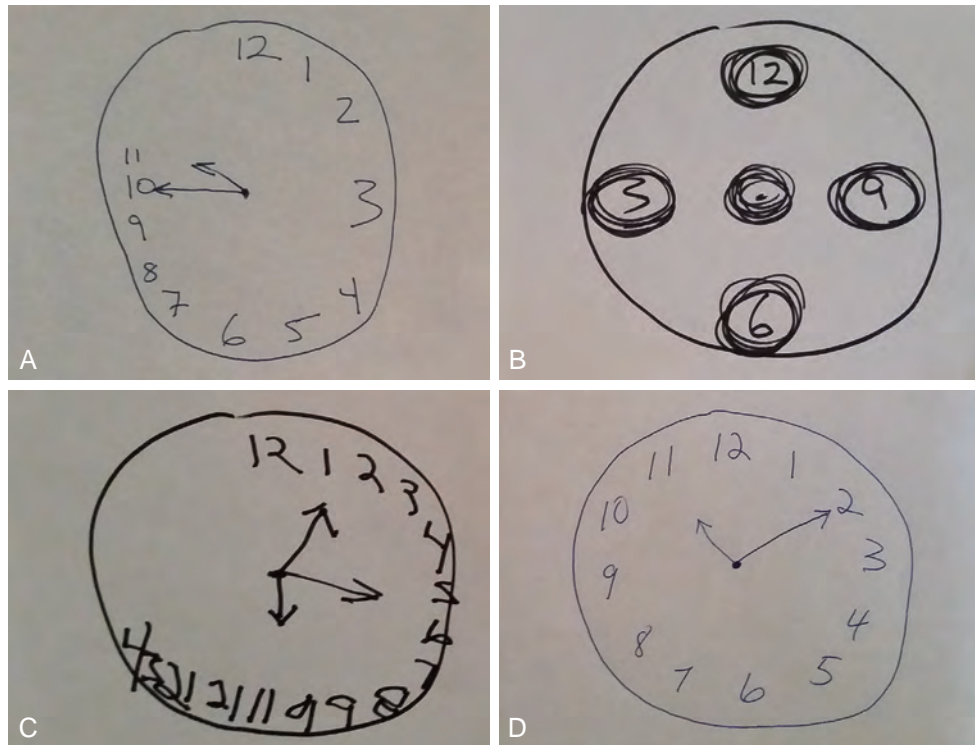

Figure 88-3. Mini-Cog clock drawing test results (abnormal and normal). Examples of the clock drawing test from the Mini-Cog assessment. **A, Abnormal.** Note the incorrect spatial orientation of the numbers and placement of the hands. **B, Abnormal.** Only four numbers are included and no hands are drawn to show time. Note the perseveration on drawing the circles around the numbers. **C, Abnormal.** Note the incorrect spatial orientation of the numbers, repetition of part of the numerical sequence, and incorrect number and placement of hands. **D, Normal.** Note the correct spatial orientation of the numbers and placement of the hands to indicate time per the instructions.

seen in urologic practice include vitamin B₁₂ deficiency, hypothyroidism, and medication side effects. Patients with a history of urinary diversion using small intestine can be at particular risk for vitamin B₁₂ deficiency, and replacement therapy may be necessary. Although not necessarily reversible, tertiary neurosyphilis can be associated with both memory loss and neurogenic bladder and voiding dysfunction.

Depression

Depression is a very common condition among older adults. As with other conditions, the incidence and prevalence both increase with advancing age, but depression should not be considered a normal or expected part of the aging process. A number of urologic health conditions have been associated with increased rates of depression, including UI and various genitourinary malignancies. The Geriatric Depression Scale (GDS) is a short, validated screening tool to assess for possible depression in older adults (Sheikh and Yesavage, 1986). The instrument consists of 15 items with yes-or-no responses. A score of 0 to 2 points is considered normal. If someone scores 3 or more points, the screening test is considered positive for possible depression. This could alert the provider to the potential need for additional evaluation. Input from the patient's primary care provider or consultation with either a geriatrician or a geriatric psychiatrist may be indicated.

Examples of urologic conditions that occur at higher rates in geriatric patients and that tend to be associated with risk for depression include UI, POP, prostate cancer, and sexual dysfunction (Kafri et al, 2013; Kahn et al, 2013; McCabe and Althof, 2014; Ravi et al, 2014). UI has been shown to be undertreated in the general older adult population and has substantial negative effects on multiple

health domains (Chang et al, 2008). Additional research is needed to identify the role of treatment of urologic conditions on mental health outcomes.

Surgical Risk and Medical Optimization

Surgical therapy remains one of the mainstays of urologic treatment for many of the clinical conditions that affect geriatric patients. Unfortunately, many clinicians and patients seem to have an inherent bias against surgical therapy for older adults. However, with careful planning, surgical therapy may be an appropriate option for treatment of many urologic conditions seen in older adults. The development of minimally invasive surgical techniques has opened up a new avenue for potential therapy for many patients. Age by itself should not be a limiting factor, and in most cases clinical comorbidity is a much more influential issue. However, even in these cases, careful preoperative planning and medical optimization can potentially reduce risk of complications after urologic surgery (Takao et al, 2008).

One of the primary tasks of the urologic surgeon planning operative care for a geriatric patient is to identify potential risks and benefits associated with surgery. Preoperative optimization should be carefully considered. Although it is technically not possible to "clear" someone for surgery, a wide variety of steps can be taken to optimize health status in different realms before surgery. The American College of Surgeons and the American Geriatrics Society (AGS) collaborated on a project to help outline evaluations that should be used before surgery in older adults (Chow et al, 2012). These recommendations are grounded on evidence-based data regarding evaluation of each organ system and various functional components. The goals of these evidence-based recommendations are to

BOX 88-1 Preoperative Assessment Recommendations for Older Adults

- Assess cognitive ability and capacity
- Screen for depression
- Identify risk factors for delirium
- Screen for alcohol and other substance use
- Perform cardiac evaluation (American College of Cardiology or American Heart Association)
- Conduct pulmonary risk assessment
- Document functional status and risk of falls
- Determine baseline frailty score
- Assess baseline nutritional status (consider preoperative replacement or supplementation)
- Obtain detailed medication history and monitor for polypharmacy
- Determine patient's treatment goals and expectations
- Determine familial and social support systems
- Order appropriate diagnostic tests and laboratory tests as clinically indicated

Modified from Chow WB, Rosenthal RA, Merkow RP, et al. Optimal preoperative assessment of the geriatric surgical patient: a best practices guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society. *J Am Coll Surg* 2012;215:453–66.

help identify risks and improve status before surgical intervention. This includes several targeted components in addition to the basic functional assessment with ADLs, IADLs, cognitive status, and mobility that have been previously described (Box 88-1) (Chow et al, 2012). Data obtained from the National Surgical Quality Improvement Program (NSQIP) were used to construct recommendations highlighted in this document.

Chronologic age is usually not identified as an independent risk factor in most research examining morbidity and mortality outcomes from surgery. However, extensive surgical time and poor baseline American Society of Anesthesiologists (ASA) classification status have been linked to worse outcomes in elderly urologic surgical patients (Peled et al, 2009). In addition, compared with elective cases, urgent and emergent surgical procedures have been shown to be associated with greater overall morbidity and mortality among geriatric patients undergoing urologic surgery (Peled et al, 2009).

Nutritional assessment is important for overall health and wound healing. One problem is that no single measure has proven adequate for complete preoperative assessment (Griebing, 2004). Different questionnaires and various biomarkers have been used. Albumin and prealbumin measure protein nutrition and are the most commonly used serum markers. Data on preoperative nutrition supplementation in geriatric patients have been variable (Evans et al, 2014). One question is whether improved nutrition can help contribute to pressure ulcer prevention (Hill-Brown, 2011). Although nutrition is a contributor to this condition, other factors such as tissue pressure and shear forces may play a stronger role. Good nutrition does appear to influence wound healing (Rosenthal, 2004; Jaul, 2010). Postoperative wound infections are a common and often preventable complication of surgery in older adults. They tend to increase both length of hospital stay and associated costs. Elderly surgical patients who experience a surgical site infection have been found to have a 3.5-times greater risk of mortality than those who do not develop this type of infection (Kaye et al, 2009). The Centers for Medicare and Medicaid Services (CMS) have included surgical site infections as one of the “never events” for which hospitals will not be reimbursed. Diminished functional status has been shown to be associated with an increased risk of

surgical wound infections (Chen et al, 2010). This is likely because of a reduction in overall functional reserve capacity, which is associated with changes in immunity and other organ system response.

Postoperative urinary retention is another very common problem that occurs frequently in geriatric patients. A wide variety of factors can increase the risk for postoperative urinary retention, including medication effects, opioid narcotics, decreased mobility, delirium, cognitive impairment, and a history of preexisting lower urinary tract anatomic and functional issues. Correction of the underlying cause will often lead to resolution of the problem, and time is an important factor in many cases (Darrah et al, 2009; Johansson and Christensson, 2010).

Anesthesia

Anesthetic considerations are important in planning for surgical interventions in geriatric urologic patients. Patients often ask if regional anesthesia would be a safer alternative than general anesthesia. Most studies to date have not shown significant differences in either morbidity or mortality among older adults undergoing surgery using regional blocks versus general anesthesia (Mason et al, 2010; Tognoni et al, 2011).

Other important anesthetic considerations include thermoregulation during surgery, fluid balance, and patient positioning. **Hypothermia during noncardiac surgery increases risk for cardiovascular and thromboembolic events** including myocardial infarction, deep vein thrombosis, and stroke. Intraoperative hypothermia has also been associated with risk of postoperative wound infection (Leeds et al, 2014). Maintenance of appropriate intraoperative patient temperatures has been identified as an essential goal and is one of the variables that is tracked for quality of hospital care in the United States. Proper fluid balance is also important, and care must be taken to avoid fluid overadministration, which can induce pulmonary edema or congestive heart failure (CHF) in older adults. Patient positioning requires careful attention to padding pressure points to prevent neuropathy, and adjusting to limitations in joint flexibility in patients with arthritis (Rozet and Valilala, 2007; Akhavan et al, 2010). Positioning patients awake before induction of anesthesia can be useful in these circumstances to prevent injury.

Cognitive changes are frequently seen immediately after anesthesia in geriatric patients. Reported rates can be as high as 56%, with 25% still having some change compared with baseline at 3 months after general anesthesia (Price et al, 2008). Although this usually resolves, in some cases cognitive changes can be more prolonged. Among older adults undergoing noncardiac surgery, advancing age, history of stroke, and lower baseline educational levels have all been associated with postoperative cognitive decline (Monk et al, 2008).

Prehabilitation

Recent research has examined the potential usefulness of preoperative conditioning and strength-building exercise in older adults. Termed *prehabilitation*, these efforts focus on improving overall conditioning, stamina, and endurance for activity. This may help to improve or at least slow the decline in functional reserve capacity. Nutritional interventions typically focus on improving protein reserves before surgical intervention. **General assessments or “eyeballing” the patient to determine level of frailty may not be adequate, and more precise measures are useful for preoperative evaluation of risk** (Hubbard and Story, 2014). Preoperative interventions have shown mixed results, and additional research will be necessary to identify optimal targets for intervention and appropriate candidates for these types of treatments.

Comprehensive Geriatric Assessment

Comprehensive geriatric assessment (CGA) is a structured method of complete health care analysis for older adults. This type of evaluation is usually conducted by a geriatrician who specializes in the primary care of older adults in conjunction with other

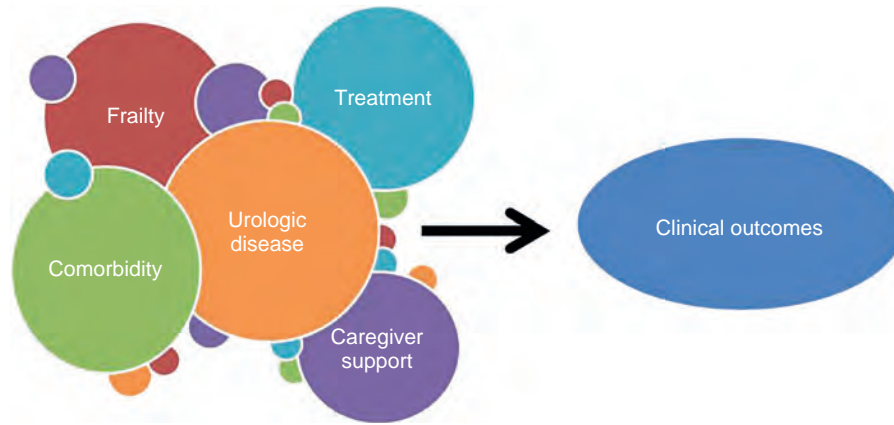

Figure 88-4. Conceptual model of health complexity and clinical outcomes in geriatrics. This schematic highlights the interrelated nature of urologic disease, comorbidity, frailty, treatment, caregiver support, and other variables. Note that these are related and influence one another but are distinct entities that do not completely overlap. Numerous other factors can contribute to and interact with these variables to influence overall clinical outcomes.

multidisciplinary health care providers including nurses, pharmacists, social workers, physical and occupational therapists, and others. Some primary care practitioners may offer CGA as part of their clinical care for geriatric patients. **Consultation and partnering with a geriatrician** in care of older adults with complex medical problems can help facilitate what can sometimes be a complex process. Similarly, **working with anesthesiology colleagues** for preoperative assessment can help to clarify clinical needs and choices of anesthetic technique in an attempt to optimize care.

There is great interest in the role of expanded assessment of geriatric patients undergoing major surgery and influence on subsequent outcomes. One study of 62 elderly women undergoing pelvic floor reconstructive surgery showed no statistically significant difference in multiple outcomes between those randomized to an enhanced CGA and those who underwent routine preoperative evaluation (Richter et al, 2005). However, the researchers noted that this may have been a result of the overall high functional and health status of women in this study. Studies with frailer and more functionally impaired older adults may yield different results. Information gleaned from CGA has been shown to be predictive of both morbidity and mortality risk after surgery (Kim et al, 2013). Geriatric patients undergoing radical cystectomy have been found to have increased complications and length of hospital stay related to underlying comorbidity and functional limitations that can be identified on careful preoperative assessment (Prentis et al, 2013). Additional research on this topic will help to elucidate the most important factors that should be included in these types of evaluations to help optimize outcomes in geriatric surgical patients.

MAJOR GERIATRIC SYNDROMES AND UROLOGY

Geriatric syndromes are defined as conditions that are complex in nature, tend to occur more commonly among older adults, are typically multifactorial, and can have substantial clinical or other outcomes for affected patients. Successful prevention or treatment often requires a multicomponent approach. Examples of geriatric syndromes include frailty, falls, pressure ulcers, polypharmacy, delirium, and UI. Different syndromes can interact and influence one another. For example, frailty is linked to falls, and both conditions are closely associated with UI. Each of these syndromes can have direct and indirect effects on urologic health in older adults (McRae et al, 2014). Data from the Health and Retirement Study on more than 11,000 older adults living in the community and nursing homes demonstrated that 49.9% had at least one geriatric syn-

drome, and presence of multiple geriatric syndromes was common (Cigolle et al, 2007). Geriatric syndromes strongly increased risk of dependency on others for completion of ADLs even after controlling for demographic factors and chronic diseases. One geriatric syndrome led to an adjusted risk ratio of 2.1 (95% confidence interval [CI] 1.9 to 2.4); for two syndromes this increased to 3.6 (95% CI 3.1 to 4.1), and for three or more syndromes to 5.6 (95% CI 5.6 to 7.6). In a cross-sectional analysis of 12,480 older adults, prevalence of geriatric syndromes among those with cancer was 60.3% compared with 53.2% in those without a history of cancer ($P < .001$) (Mohile et al, 2011). This highlights the complexity of these conditions and overlap with other health issues associated with aging.

Frailty

Frailty is a complex condition frequently seen in elderly patients that is becoming better understood with ongoing research. It is not age dependent and can also occur in younger people, although incidence and prevalence both increase with advancing age. **It overlaps with but is not completely identical to the concepts of comorbidity or disability (Fig. 88-4).** *Comorbidity* refers to presence of other health states or conditions. Examples would include diabetes or hypertension. *Disability* refers to need for assistance from others to accomplish various tasks. An example would be the need to have someone help with bathing, dressing, or using the toilet. Potential relationships between preoperative frailty and postoperative outcomes have recently garnered increased research attention (Revenig et al, 2013).

Several different definitions and conceptual models of frailty exist, and these differ somewhat based on theoretic components they include. One causation theory is an accumulated deficits model. In this conceptual framework, multisystem deterioration is combined with reduced functional reserve capacity. Accumulated deficits can be counted numerically, and increased summative scores indicate a higher degree of frailty. In this model, frailty tends to progress with cyclic deterioration over time and with more added deficits. The Deficit Accumulation Index (DAI) has been used in an attempt to identify preoperative levels of frailty and predict subsequent outcomes (Braden and Bergstrom, 1994; Cohen et al, 2012). However, the DAI was not found to be statistically predictive of outcomes in this study. This indicates that a simple numerical scoring of deficits may not be adequate, and interactions among components are more complex.

Although different operational definitions of frailty have been proposed, one of the more commonly used is the conceptual model

developed by Fried and colleagues, which includes measureable changes for five different components (Fried et al, 2001). This frailty phenotype includes unintentional weight loss of more than 10 pounds or more than 5% of total body weight in 1 year, reduced grip strength, slowing of gait speed and mobility, decreased overall levels of activity, and a sense of easy exhaustion with activity. Individuals with three or more components are considered “frail,” those with one or two components are classified as “pre-frail,” and those with none of the components are “non-frail.”

The predictive value of frailty assessment in older urologic patients, particularly those being considered for surgery, has been the subject of recent research. Frailty evaluation can be accomplished relatively easily in outpatient clinical settings, and results can be predictive of both morbidity and mortality outcomes in elderly surgical patients (Ravaglia et al, 2008; Makary et al, 2010; Kim et al, 2014a). Data derived from electronic medical records can be used, although these may not provide complete information in all cases (Amrock et al, 2014). Inclusion of cognitive changes in addition to physical assessment has been shown to improve predictive value for clinical outcomes among hospitalized older adults (Wou et al, 2013).

Translational research studies have attempted to identify a relationship between various inflammatory biomarkers and the frailty phenotype. Increased levels of interleukin-6 (IL-6), D-dimer, C-reactive protein, white blood cell count, and others have been described in correlation with increased frailty (Chang et al, 2012c; Fontana et al, 2013). There is some debate over whether low levels of inflammatory response may actually be beneficial, particularly for wound healing, but that higher levels may be destructive because of oxidative stress.

Falls

Older adults are at an increased risk for falls and associated injuries including long bone and hip fractures. UI and use of indwelling urinary catheters have both been identified as risk factors for potentially injurious falls (Brown et al, 2000; Chiarelli et al, 2009; Foley et al, 2012). Similarly, LUTS including OAB have been shown to increase fall risk in community-dwelling older adults and those requiring home care services (Hunter et al, 2013; Kurita et al, 2013). In long-term care facilities, UI and behavioral changes associated with cognitive decline and dementia have been identified as independent risk factors for falls in older adults (Hasegawa et al, 2010). Nocturia can also play a role (Galizia et al, 2012). Contributing clinical and environmental factors include orthostatic or postural hypotension, vertigo, gait and balance problems, poor lighting, physical obstacles, or long distance between the bed and toilet. Urinary urgency is a common risk factor for falls as a result of nocturia or urgency UI. When older adults attempt to rush to the toilet, fall risks increase. Slipping on wet floors caused by urine leakage can also occur. Additional identified risk factors for falls include visual and other sensory impairments, alterations in cognitive status, and delirium.

Urinary catheters have been shown to increase risk of falls in older adults. Similarly, other **physical restraints** have been associated not only with increased falls but other potentially dangerous injuries including strangulation and accidental death. **Physical restraints should be avoided if at all possible**, and efforts targeted at reducing their use have been quite beneficial in nursing home and other care settings. Other interventions designed to improve overall care in long-term care facilities have also been shown to improve outcomes and decrease risk of falls associated with UI in this setting (Min et al, 2011).

Elderly men on androgen deprivation therapy (ADT) are at particularly increased risk for fractures and other injuries associated with falls (Bylow et al, 2008). Hormonal manipulation with androgen deprivation is associated with decreases in bone mineral density and an increased risk of development of osteopenia and osteoporosis. This causes bones to be more brittle and increases risk of fracture during falls. Elderly men with associated LUTS resulting from BPH or other conditions have been shown to have higher rates

of falls and fractures than men without these urologic conditions (Parsons et al, 2009).

Pressure Ulcers

Pressure ulcers are areas of localized tissue necrosis that typically occur over bony prominences as a result of prolonged pressure against a hard surface. Tissue shearing can also occur with movement and transfers. Changes in skin anatomy and integrity occur as a part of the general aging process, with a decrease in the amount of elastic tissue and alterations in collagen and other connective tissue quality. In addition, older adults often have decreased sensation in cutaneous tissues and may be prone to increased rates of underlying skin infections. These factors all increase the risk of pressure ulcer formation in older adults. **UI is another common factor that increases pressure ulcer risk in older adults.** Maceration of tissues from chronic moisture can lead to progressive tissue loss, particularly when combined with physical pressure or shearing forces.

Positioning and transfers during surgery in older adults are especially important. Care must be taken to adequately pad all pressure points during surgery, and efforts made to eliminate shearing effects during transfers between beds and transport carts. Many older adults have arthritis, and this can make positioning for surgery challenging, particularly in the dorsal lithotomy position. In these cases, positioning the patient while awake before induction of anesthesia can be quite useful to help confirm a comfortable position and prevent injury.

Early mobilization and physical activity after surgery are important for many reasons, including reducing the risk of pneumonia, deep vein thrombosis, pulmonary embolus, and pressure ulcers. Even among healthy younger people, extended bed rest is associated with substantial loss of mobility, aerobic capacity, and lower extremity strength (Kortebein et al, 2008). These negative effects are compounded in older adults, who may start at diminished baseline functional levels. Frequent turning of patients who are in bed or using a wheelchair is another important prevention method. Use of specialized air mattresses or other pressure reduction methods also helps reduce risk.

Pressure ulcers are staged based on clinical characteristics. Stage I ulcers include nonblanching erythema of intact skin. Stage II ulcers include partial thickness skin loss but do not involve muscle or other deeper tissues. These can appear as an abrasion, blister, or shallow crater. Stage III ulcers involve full-thickness skin loss that may extend to but not through the underlying fascia. Stage IV ulcers are characterized by extension into deeper tissues, including muscle or bone, with possible exposure of supporting structures such as tendons.

It is important to carefully document skin integrity in older adults being admitted to hospital care. CMS has designated new pressure ulcer formation as one of the “never events” that is considered preventable in essentially all cases. Accordingly, they will not reimburse facilities or providers for care for new pressure ulcers.

The prevalence of pressure ulcers among hospitalized elderly patients has been reported to be as high as 8.9% (Barrois et al, 2008). **Urinary, fecal, and dual incontinence have been identified among the strongest risk factors for the development of pressure ulcers in the elderly population.** Clinicians should have a high index of suspicion for the risk of pressure ulcers, and careful examination should be performed as part of the routine physical examination in older adults with bladder and bowel incontinence. Among hospitalized older adults, increased length of time waiting in the emergency room, immobilizing procedures or medications, and intensive care unit stays have all been identified to increase the risk of developing pressure ulcers (Baumgarten et al, 2008).

Polypharmacy and Medication Optimization

Polypharmacy is a highly prevalent and complex geriatric syndrome that has been defined in a number of different ways. The simplest definition is the use of multiple medications. More recent

definitions include the concepts of increased regimen complexity and use of potentially inappropriate medications (PIMs). More complex medical regimens may be difficult for older adults to follow correctly and can lead to poorer compliance with prescribed therapy. Risk of drug interactions increases exponentially with increased numbers of medications. Use of inappropriate medications can lead to untoward side effects and other negative outcomes (O'Connor et al, 2012). Rates of PIM prescription among older adults are high, with approximately 25% of more than 272,000 patients in one study being on PIMs in the perioperative period (Finlayson et al, 2011). The ultimate goal is to optimize pharmacotherapy and minimize risk in older adults using medications. **The practice of medication reconciliation during hospitalization and clinical evaluation has become a common practice and is an important step in helping to reduce or eliminate polypharmacy in geriatric patients.** During this process, all medications including prescription and nonprescription medications are assessed. Clinical indications for each medicine are verified, and response determined. Ideally, medications without a clear clinical indication should be discontinued. PIMs should also be identified, and safer agents substituted if possible. In addition, medication underuse can occur with elderly patients, and it is important to recognize when medications might be clinically indicated based on guidelines or other evidence-based practice.

In 1993, the late Dr. Mark Beers convened a consensus panel to develop a listing of potentially inappropriate medications for use in older adults in nursing home settings. This original listing has been updated and expanded over time to include all older adults and is no longer limited by location or type of clinical care. **The AGS has recently published a revised version of the Beers Criteria (AGS Beers Criteria Update Expert Panel, 2012).** This is a highly evidence-based document that categorizes medications into different groups based on characteristics and considerations for use in older adults. The most recent version includes information on level of evidence used to make recommendations, and overall strength of the recommendation from the expert panel. The plan is that this document will be regularly updated as new data on medications become available.

Some medications are considered always inappropriate for elderly patients and should be avoided in all cases. An example of such a medication often used in urologic practice is meperidine (Demerol). This drug was included because of the significant potential risks for delirium and other adverse events caused by accumulation of a toxic metabolite, poor overall efficacy, and availability of other more clinically useful alternatives. Other urologic medications are included in portions of the AGS Beers Criteria document. For example, antimuscarinic agents used in treatment of OAB and

urgency UI are included in a group of medications to avoid with specific comorbid conditions; these medications should be avoided or used with caution in older adults with a history of chronic constipation or cognitive impairment. Nitrofurantoin is included as a medication to avoid in older adults with impaired renal function (GFR below 60 mL/min) or for chronic prophylaxis because of the potential risk of pulmonary fibrosis. It is acceptable for treatment of acute UTIs and other short-term indications in patients with adequate renal function. A summary of medications commonly used in urologic practice included in the 2012 AGS Beers Criteria is presented in Table 88-1.

Medications with anticholinergic effects deserve special mention. There are a large number of different medications that can have potential anticholinergic effects in older adults. This is in part because of cross-reactivity among different types of receptors located in different organs including salivary gland, bowel, and bladder. Common anticholinergic effects in older adults include dry mouth, constipation, dry eye, and confusion. Several studies have examined the concept of total anticholinergic burden in older adults. Increased anticholinergic burden can worsen underlying cognitive function, memory, and associated comorbid conditions such as Alzheimer disease (Han et al, 2008; Fox et al, 2011a, 2011b). Serum studies have shown that total anticholinergic burden can be measured, although listings of medications must be used in conjunction with this to improve diagnostic accuracy (Lampela et al, 2013). Attempts should be made to reduce or eliminate use of anticholinergics to the greatest extent possible. Reductions in overall anticholinergic burden have been associated with improvements in behavioral and cognitive outcomes in affected elderly patients (Kersten et al, 2013). When these medications are used for a clinically indicated purpose, response should be closely monitored to determine if an appropriate effect is achieved, and the medication discontinued or changed if warranted.

A basic principle for prescribing medications in the geriatric patient population is to "start low and go slow." This refers to the fact that lower medication doses may be effective in older adults compared with younger patients, and that high initial doses can often have adverse effects. Starting with lower doses and gradually increasing medication dosage with time can help to alleviate some of these potential problems. **One caveat that needs to be considered is that medication dose may need to be increased to reach the point of clinical efficacy.** Therefore care should be taken to avoid keeping doses of medications so low that they are not actually effective for symptoms they are prescribed to treat. Dose escalation should be continued until a clinically effective end point, maximum dose for a particular medication, or intolerable side effects are reached.

TABLE 88-1 Select Medications Commonly Used in Urology Included in the 2012 Beers Criteria

MEDICATION	RECOMMENDATION	RATIONALE	QUALITY OF EVIDENCE	STRENGTH OF RECOMMENDATION
α_1 -Blockers <ul style="list-style-type: none"> • Doxazosin • Prazosin • Terazosin 	Avoid use as an antihypertensive (all patients) Avoid use in women with stress UI	Not recommended as routine treatment for hypertension; alternative agents have superior risk-benefit profile; high risk of orthostatic hypotension; may aggravate stress UI in women.	Moderate	Strong
Nitrofurantoin	Avoid for long-term suppression Avoid in patients with CrCl below 60 mL/min	Safer alternatives available; potential for pulmonary toxicity; lack of efficacy in patients with CrCl below 60 mL/min because of inadequate drug concentration in urine.	Moderate	Strong

TABLE 88-1 Select Medications Commonly Used in Urology Included in the 2012 Beers Criteria—cont'd

MEDICATION	RECOMMENDATION	RATIONALE	QUALITY OF EVIDENCE	STRENGTH OF RECOMMENDATION
Tertiary tricyclic antidepressants, alone or in combination <ul style="list-style-type: none"> Amitriptyline Imipramine 	Avoid	Highly anticholinergic and sedating and cause orthostatic hypotension.	High	Strong
First-generation antihistamines (as single agent or as part of combination products) <ul style="list-style-type: none"> Diphenhydramine (oral) Hydroxyzine Promethazine 	Avoid	Highly anticholinergic; clearance reduced with advanced age, and tolerance develops when used as a hypnotic; anticholinergic effects and toxicity. Use of diphenhydramine in special situations such as acute treatment of severe allergic reaction may be appropriate.	High: hydroxyzine and promethazine Moderate: diphenhydramine	Strong
Androgens <ul style="list-style-type: none"> Methyltestosterone Testosterone 	Avoid unless indicated for moderate to severe hypogonadism	Potential for cardiac problems and contraindicated in men with prostate cancer.	Moderate	Weak
Estrogens with or without progestins	Avoid oral or topical patch; topical vaginal cream acceptable use for management of dyspareunia, lower urinary tract infections, and other vaginal symptoms	Evidence of carcinogenic potential (breast and endometrium) and aggravation of UI for oral or transdermal; lack of cardioprotective effect and cognition protection in older women. Evidence that vaginal estrogens for treatment of vaginal dryness are safe and effective in women with breast cancer, especially at doses of estradiol below 25 µg twice weekly.	High: oral and patch Moderate: topical	Strong: oral and patch Weak: topical
Anticholinergics Benzodiazepines Meperidine	Avoid in patients with or at high risk of delirium	Can induce or worsen delirium.	Moderate	Strong
Anticholinergics Benzodiazepines	Avoid in patients with dementia or cognitive impairment	Can cause adverse central nervous system side effects.	High	Strong
Meperidine	Avoid as an analgesic	Not an effective oral analgesic in commonly used doses; may cause neurotoxicity; safer alternatives available.	High	Strong
Oral antimuscarinics for UI <ul style="list-style-type: none"> Darifenacin Fesoterodine Oxybutynin (oral) Solifenacin Tolterodine Trospium 	Avoid in patients with chronic constipation (unless no other alternatives are available)	Can worsen constipation; antimuscarinics overall differ in incidence of constipation; response variable; consider alternative agent if constipation develops.	High	Weak
Inhaled anticholinergic agents	Avoid in men with LUTS and/or BPH	May decrease urinary flow and cause urinary retention.	Moderate	Strong

Note: This is *not* a complete listing of all medications included in the 2012 Beers Criteria.

BPH, benign prostatic hyperplasia; CrCl, creatinine clearance; LUTS, lower urinary tract symptoms; UI, urinary incontinence.

Modified from American Geriatrics Society (AGS) Beers Criteria Update Expert Panel: American Geriatrics Society Updated Beers Criteria for Potentially Inappropriate Medication Use in Older Adults. J Amer Geriatr Soc 2012;60:616–31. Please see this citation for detailed information.

It is also important for clinicians to avoid the “prescribing cascade.” In this situation a patient is prescribed a medication for a clinical problem. Because of side effects from this medication, the patient develops new symptoms that are attributed to a different cause, leading to prescription of a second medication to treat the side effects. To avoid this problem, clinicians should consider whether a new symptom might be the result of a medication side effect rather than another cause. The American Geriatrics Society has included the concept that a medication review should be performed any time a new prescription is given as part of their Choosing Wisely list (AGS Choosing Wisely Workgroup, 2014).

Delirium

Delirium is an extremely important geriatric syndrome to consider in older urologic patients. Delirium is defined as an acute confusional state characterized by fluctuations in mental status and inattention. In addition, patients must exhibit either disorganized thinking or an altered level of consciousness. This most commonly manifests in the form of agitation; however, a hypoactive form can also occur. Patients may experience hallucinations or delusions. These symptoms can be quite disturbing to patients, loved ones, and clinical care providers. Agitated patients tend to act out physically or emotionally, and the behavior can usually be easily recognized. The hypoactive form of delirium can be much more subtle and difficult to diagnose. However, there are data to suggest that hypoactive delirium actually may be more dangerous in terms of negative sequelae including risk for mortality (DeCrane et al, 2011).

Delirium is highly prevalent and is associated with substantial negative outcomes. However, the condition is often under-recognized in this population (Vollmer et al, 2010). Rates of developing postoperative delirium range from 10% to 15% after noncardiac surgery and increase in cases of either urgent or emergency surgical procedures (Demeure et al, 2006). Patients who develop delirium postoperatively have a twofold to threefold increase in the risk of mortality within the first year after surgery (McCusker et al, 2002; Ely et al, 2004). There is also an increased risk of progressive cognitive decline and potential need for placement in nursing home care at the time of hospital discharge in patients who develop an episode of delirium (Rudolph et al, 2008; Popejoy et al, 2013).

There are multiple risk factors for development of delirium in geriatric patients. Examples include electrolyte abnormalities, pain, sensory impairment, immobility, dehydration, sleep deprivation, pneumonia or other infections, and alcohol withdrawal. Having had a prior episode of delirium is also a strong risk factor for future delirium. Patients with underlying dementia are also at higher risk. Acute UTIs in older adults may be a cause for delirium, and urinary samples including cultures should be checked as part of the evaluation if this is suspected (Eriksson et al, 2010). In a study of urologic surgical patients, poorer baseline functional status and older age were identified as risk factors for delirium, but type of anesthesia (regional vs. general) and mode of surgery (open vs. endoscopic) were not (Tognoni et al, 2011). Some medications, including statins, have been identified as another potential risk factor in surgical patients (Redelmeier et al, 2008).

Inouye and colleagues developed and validated the Confusion Assessment Method (CAM) as a way to identify and diagnose delirium (Inouye et al, 1990). These diagnostic criteria require that patients exhibit an acute change in mental status with a fluctuating course and inattention. In addition, they must also exhibit either disorganized thinking or an altered level of consciousness. The CAM has been used in numerous clinical settings and has been shown to be easy to use and interpret. Using these criteria, delirium can be diagnosed with 94% to 100% sensitivity and 90% to 95% specificity (Inouye, 2006).

Several studies have examined the effects of delirium on clinical outcomes in older adults including those developing the condition after surgery. In one study of 49 geriatric patients undergoing radical cystectomy, the incidence of postoperative delirium was 29%, and readmission and reoperation rates were both higher in those who

developed delirium compared with those who did not (Large et al, 2013).

Prevention of delirium is key, and clinicians should have a high index of suspicion for diagnosis in patients who exhibit signs or symptoms of the condition. Some medications are known to substantially increase risk of delirium in older adults, including sedative hypnotics, anticholinergics, and opioid narcotics. Care must be taken to control pain but also to avoid inducing delirium caused by medications. Pain itself is a risk factor for development of delirium, and this must be carefully assessed and managed. In patients with underlying cognitive impairment such as dementia, pain can be difficult to assess accurately (Horgas et al, 2009). Patient-controlled analgesia (PCA) offers the potential benefit of avoiding overdosage of medication, provided only the patient is pushing the administration button on the device. However, proper use of PCA requires a cognitively intact patient who understands the therapy and is able to self-administer medication when needed to control pain.

Treatment for delirium includes methods to reduce disruption and improve sensory interaction with the patient and his or her surroundings. This includes maintaining proper sleep-wake cycles, minimizing distractions including alarms and other loud noises, having family or other loved ones at the bedside to help reorient the patient, making sure a patient's hearing aids and glasses are provided, and assisting with mobility. Underlying fluid and electrolyte imbalances should be corrected. In patients who present a physical danger to themselves or care workers, temporary physical or chemical restraint may be necessary. **The preferred medication treatment is haloperidol administered intravenously in small doses, usually starting at 0.25 or 0.5 mg.** Doses may be repeated at approximately 15-minute intervals until the patient is calm. A total dose of 1 to 2 mg or more may be required, but it is safer to administer this in progressive small quantities and monitor for response rather than giving a large bolus dose, which could be too sedating. Other benzodiazepines or sedative hypnotics should be avoided in general because of potential adverse effects including worsening of delirium, severe sedation, or an increase in associated delusions or hallucinations. Physical restraints should be used only with extreme caution and for short time periods and are indicated only if the patient is in imminent danger of harming himself or herself or others.

Costs associated with postoperative delirium in geriatric surgical patients are quite high. Development of delirium, even subsyndromal delirium, is associated with increased rates of hospital readmission, reoperation, caregiver requirements, and need for institutionalization (Cole et al, 2008; Large et al, 2013). Economic analysis has shown an approximately 2.5-fold increase in costs for elderly patients who experience an episode of delirium while in the hospital compared with those who do not develop delirium (Leslie et al, 2008).

Urinary Incontinence

The International Continence Society (ICS) defines *urinary incontinence* as the involuntary loss of urine (Abrams et al, 2002). **From a clinical perspective, UI can be considered both a specific diagnosis and a geriatric syndrome.** This is particularly true among frail older adults, who may have multiple chronic conditions and geriatric syndromes (Fonda et al, 2005; DuBeau et al, 2010; Wagg et al, 2013b). Urologists and gynecologists tend to view UI as a clinical diagnosis, in contrast to geriatricians who conceptualize it more as a geriatric syndrome. As previously described, geriatric syndromes are defined as common conditions seen in older adults that are complex in nature, are usually multifactorial, and can have substantial clinical or other negative health outcomes for affected patients.

The incidence and prevalence of UI both increase in older adults. However, incontinence should not be considered a normal or inevitable part of the aging process. Just because someone is elderly or frail does not mean that they should experience UI. This is a common myth among both health care providers and patients that

needs to be dispelled. UI is more commonly associated with underlying medical conditions or other factors rather than chronologic age itself.

Negative Impacts of Urinary Incontinence

UI can have substantial negative health outcomes in older adults (Dugan et al, 2000). The condition is associated with social isolation, depression, stigmatization, and embarrassment for many affected patients. Many people discontinue activities that they enjoy because of urinary leakage. They may stop going out to the theater or to movies, stop attending church or temple, or stop visiting friends because of the condition. Incontinence can also have important negative physical effects. Chronic incontinence can be associated with skin irritation and breakdown, development or worsening of pressure ulcers, UTIs, and falls and fractures. UI also has effects on mental health, including increased rates of depression among affected older adults (Laganà et al, 2014). Research has shown that UI has a stronger negative influence on overall levels of happiness than many other common chronic conditions in older adults, including diabetes, hypertension, arthritis, and osteoporosis (Angner et al, 2009). Only chronic debilitating pain has been shown to be a stronger negative predictor of diminished happiness.

Costs of Incontinence

The direct and indirect financial costs of UI are staggering. Medicare expenditure data showed that costs of care for UI nearly doubled from \$128 million in 1992 to \$234 million in 1998 (Anger et al, 2006). This represents a 15% per capita increase in treatment costs once adjusted for inflation. Other economic analysis has shown an estimated national cost of evaluation and care for OAB with urgency UI of \$65.9 billion in 2007 with projected increases to \$76.2 billion in 2015 and \$82.6 in 2020 (Coyne et al, 2014). It must be noted that this includes care for patients of all ages, not just older adults. Recent analysis has shown increasing rates of office visits, hospitalization, and other resource utilization for UI, which also tend to drive up associated costs (Thom et al, 2005). The estimated annualized cost in 2000 for nursing home admissions as a result of UI was \$6.0 billion (Morrison and Levy, 2006). In addition, there are substantial environmental costs associated with use of absorbent pads and products going into landfills.

UI can have substantial negative effects on both general and health-related QoL in older adults. It limits the ability of people to participate in leisure activities and engage with others in the community (Kwong et al, 2010). Many older adults will stop participating in activities they enjoy owing to fear or embarrassment about urinary leakage. The associated psychosocial effects can be substantial and include problems with depression and social isolation (Pintarelli et al, 2011; Chung et al, 2013; Lee et al, 2013b; Yip et al, 2013; Sahin-Onat et al, 2014). Depression can be particularly problematic among older adults and can cause issues in other facets of life including mental health domains, nutrition and eating, sleep quality, and happiness (Angner et al, 2009; Sexton et al, 2011).

UI can cause significant psychological distress for elderly patients, often because of their reduction in other activities (deVries et al, 2012). Many older adults require assistance with toileting and other ADLs. Levels of caregiver burden can also be substantially higher among those with associated UI, particularly if other ADL impairments are present (Gotoh et al, 2009; Miu et al, 2010; Tamanini et al, 2011). The type of UI may influence outcomes related to QoL, particularly for those with mixed symptoms (Frick et al, 2009). However, other epidemiologic studies in older adults have shown that the degree of incontinence as measured by severity appears to be more influential on health-related QoL outcomes than type of UI (Aguilar-Navarro et al, 2012; Barentsen et al, 2012).

Among older adults living in nursing homes, UI has been shown to have negative impact on a number of important QoL parameters including dignity, autonomy, and mood (Xu and Kane, 2013). Successful treatment of UI has been shown to substantially improve health-related QoL outcomes (Fonda et al, 1995).

Transient Urinary Incontinence

UI in older adults is frequently transient in nature. In fact, studies indicate that up to 30% of UI in community-dwelling older adults and nearly 50% of UI in elderly patients admitted to acute care hospitals may be caused by transient conditions (Resnick et al, 1988; Herzog and Fultz, 1990). The identification of transient incontinence among elderly patients is important because it highlights the interplay between various organ systems and genitourinary function. For example, if a patient develops worsening peripheral edema because of an exacerbation of CHF, this could increase nocturnal urinary production and associated nocturia or nocturnal enuresis. Similarly, temporary mobility impairment from lower extremity cellulitis in a patient with detrusor overactivity (DO) and urinary urgency may lead to development of urgency UI. Although no direct changes occurred in bladder function in either example, changes in fluid volume or mobility status led to urinary leakage. Treatment of underlying causative conditions could result in improvement or complete resolution of UI. Prospective evaluation and treatment for these conditions in elderly patients have been shown to be effective (Resnick, 1989).

A wide variety of conditions can lead to associated transient UI. Patients with sudden or new onset of UI symptoms should be screened for possible associated causative conditions. However, even patients with longstanding UI can be affected if these underlying conditions have been present but untreated over time. Multiple causes are frequently involved in geriatric patients.

Detailed information on specific causes of transient UI in older adults is included on the Expert Consult website.

Established Urinary Incontinence

Established or chronic UI is an extremely common problem in geriatric patients. Recent epidemiologic data show that of all people over 65 years of age, 43.8% report a history of any urinary leakage (Gorina et al, 2014). Among community-dwelling elderly women, 12% report severe or very severe UI. More than half of community-dwelling women and about a quarter of men report experiencing UI. Overall, 36.6% of those in residential care facilities, not including nursing homes, experienced UI, and women were 1.2 times as likely to report this as men (95% CI 1.03 to 1.4). Similarly, of those older adults receiving home care services, 40.2% reported problems with bladder control, and women were 1.7 times more likely to experience this than men (95% CI 1.3 to 2.1) (Gorina et al, 2014). **Types of Established Urinary Incontinence.** The major categories of established UI in older adults are similar to those in younger people, although there are some important clinical caveats that must be noted (Diokno, 1990).

Urge UI is the most common form of established incontinence among elderly people. This is typically associated with symptoms of urinary urgency and frequency. DO is often seen on urodynamic evaluation and is a common cause among older adults (Griebling, 2013b). The ICS defines *urge incontinence* as the complaint of involuntary leakage accompanied by or immediately preceded by urgency and *detrusor overactivity* as a urodynamic observation characterized by involuntary detrusor contractions during the filling phase, which may be spontaneous or provoked (Abrams et al, 2002). Although the exact cause of DO is unclear, a number of different theories and mechanisms associated with aging have been explored. These include bladder and pelvic organ ischemia, free radical release and tissue damage from oxidative stress, inflammatory effects, changes in both central and peripheral neural control, and cellular dysfunction (Smith, 2010; Young et al, 2013; Chancellor, 2014; Tyagi et al, 2014a).

Normal urine storage and voiding are complex processes that require synchronous interaction between the bladder and peripheral and central nervous systems. Interaction between brain activity and bladder function in older adults has been the subject of research interest (Griffiths et al, 2005, 2007). Studies have used both static and functional magnetic resonance imaging (MRI), sometimes done in conjunction with urodynamic studies, to assess these

UTI causes an inflammatory reaction in the urothelium, which can lead to increased sensations of bladder filling. This causes urinary frequency and in some cases urinary UI. This should be considered symptomatic and should be evaluated and treated appropriately. In contrast, true asymptomatic bacteriuria does not by itself cause UI and does not require antibiotic therapy. Atrophic vaginitis or urethritis is common in elderly women and may be associated with dysuria or a burning sensation with voiding. Physical examination reveals thinning and loss of rugation of vaginal mucosa, although inflammatory changes with erythema and mucosal hemorrhage may also be seen in a minority of patients. In elderly women who are sexually active, atrophic vaginitis can lead to dyspareunia. Treatment with vaginal estrogens can help ameliorate symptoms of this condition and may help improve continence status in affected individuals. It also helps reduce incidence of symptomatic UTIs in postmenopausal women (Goldstein et al, 2013).

Fecal impaction is frequently seen in older adults. This can be caused by slow transit time through the gut or increased water reuptake in the colon. Fecal incontinence (FI) and diarrhea may be presenting symptoms because liquid stool proximal to the impaction moves around the impacted stool bolus. Disimpaction often results in resolution of both urinary and fecal symptoms. Chronic constipation is a common problem in older adults. Treatment and prevention with a bowel regimen can help. This typically involves multiple modalities including stool softeners, an increase in dietary or supplemental fiber, increased fluid intake, and judicious use of products such as polyethylene glycol (MiraLax) (Schnelle et al, 2010).

Numerous different medications can cause transient incontinence in older adults including psychotropics, diuretics, benzodiazepines, angiotensin-converting enzyme (ACE) inhibitors, calcium channel blockers, tricyclic antidepressants, methylxanthines, α -blockers, narcotic analgesics, and others (Landi et al, 2002; Tsakiris et al, 2008; Kashyap et al, 2013). Polypharmacy is a common problem in older adults that has also been linked to increased risk of UI (Talas and Lechleitner, 2012). Diuretics are commonly prescribed for treatment of hypertension or peripheral edema but cause an increase in urinary production that can overwhelm the bladder and cause urinary urgency, frequency, and urgency UI (Peron et al, 2012). If taken at night, diuretics can potentially induce nocturia and nocturnal enuresis. ACE inhibitors, also used to treat hypertension, can induce cough and worsen stress UI, particularly in older women. Combinations of these medications for treatment of hypertension have been shown to have synergistic effects in worsening UI in older adults (Peron et al, 2012). Opioids and narcotic analgesics tend to decrease detrusor contractility and can cause urinary retention with associated incontinence. Cholinesterase inhibitors prescribed to help slow progression of memory loss in Alzheimer dementia can increase detrusor contractility, leading to symptomatic UI (Hashimoto et al, 2000). Tricyclic antidepressants can exert a strong anticholinergic effect and decrease detrusor contractility, leading to difficulty voiding or urinary retention. The α -adrenergic receptor antagonists cause smooth muscle relaxation and can worsen stress UI, particularly in women.

Data from the Women's Health Initiative study demonstrated that systemic administration of estrogen was actually associated with increased rates of UI (Hendrix et al, 2005). It is one reason that systemic estrogen is usually not encouraged in elderly women. The most recent update of the AGS Beers Criteria also includes a recommendation to avoid systemic estrogens in elderly women because of this increased risk of UI (AGS Beers Criteria Update Expert Panel, 2012). Alcohol and other substance abuse should also be considered as a potential cause of UI. Anticholinergic medica-

tions can worsen UI by exacerbating urinary retention and incomplete bladder emptying. This in turn can lead to greater urinary frequency as the bladder reaches capacity quickly even after voiding. In addition, older adults may have decreased salivary secretions, which can be worsened by anticholinergic medications. Increased fluid intake in response to this dry mouth can worsen incontinence symptoms. Over-the-counter decongestant medications used to treat colds and flu often have strong anticholinergic properties. These can worsen urinary retention, particularly in men with underlying BPH and some degree of BOO.

Psychological or behavioral factors including depression or anxiety can lead to changes in continence status (Steers and Lee, 2001). Successful treatment of underlying psychological issues may help reduce or resolve UI. Similarly, delirium or dementia can cause incontinence as a result of cognitive changes. In delirium, these are typically associated with acute confusion and fluctuation in status and inattention. Dementia tends to be more long-standing and progressive over time but can also be associated with substantial cognitive change and inattention to voiding (Lee et al, 2014). Although dementia may not be reversible, acute delirium is typically treatable and UI may resolve with abatement of acute cognitive changes.

Mobility impairment can cause problems with UI (Kim et al, 2015). This can result from either acute or chronic conditions. Hip and long bone fractures, arthritis, joint deformities, spinal stenosis, and claudication can significantly limit mobility. Other gait and balance problems include disequilibrium, vertigo, orthostatic or other forms of hypotension, generalized deconditioning, and muscle weakness. Visual impairment and other sensory limitations can increase fear of falling and result in reduction of mobility. Stroke often leads to mobility impairment, which may or may not improve with time and rehabilitation.

Normal pressure hydrocephalus is a condition seen more commonly in older than in younger adults. The condition is characterized by a triad of symptoms including ataxic gait, cognitive dysfunction, and UI. Ventriculoperitoneal (VP) shunt placement is the main therapy for normal pressure hydrocephalus and may lead to complete resolution of symptoms, particularly if patients are treated relatively early after onset of symptoms (Akiguchi et al, 2008). Other neurologic disorders can lead to problems with UI in elderly patients. Parkinson disease is often associated with sleep disorders and may increase nocturia (Vaughan et al, 2013). It also increases risk of urinary urgency and DO. UI is particularly common in older adults with Alzheimer disease, Lewy body dementia, and vascular dementia (Sakakibara et al, 2005; Ransmayr et al, 2008).

Excess urinary output, polyuria, can also lead to transient UI. In addition to diuretics, other potential causes include metabolic derangements, CHF, pulmonary edema, venous insufficiency, malnutrition with hypoalbuminemia, diabetes insipidus, syndrome of inappropriate antidiuretic hormone production (SIADH), or excessive fluid intake as a result of psychogenic polydipsia or other factors. Peripheral edema can cause increased urine production when the patient moves to a recumbent position and tissue fluid recirculates, leading to increased urinary production. Affected patients may benefit from elevating their legs above heart level late in the afternoon to off-load some of this excess fluid before retiring to bed, thus reducing nocturia. Numerous medications can also exacerbate the development of peripheral edema including thiazolidinediones or glitazone medications used to treat diabetes, amantadine used to treat Parkinson disease, β -blockers, calcium channel blockers, and nonsteroidal anti-inflammatory drugs (NSAIDs).

relationships (Krhut et al, 2012; Tadic et al, 2012; Morris, 2013). Normative data examining continent younger and elderly women have been obtained using functional MRI scanning during bladder filling and voiding (Griffiths et al, 2009). These include data on both motor and sensory changes in control patients associated with small filling volumes, often associated with urgency in symptomatic patients (Tadic et al, 2013). In contrast to asymptomatic controls, patients with a history of urinary urgency, frequency, and UI tend to have an increase in white matter hyperintensities on brain MRI (Kuchel et al, 2009; Wehrberger et al, 2013). These findings support the hypothesis that alterations in brain anatomy and physiology may play a crucial role in urinary control in older adults. Additional research will help to further elucidate these complex processes and may identify future targets for therapy.

UI is particularly common after stroke. Approximately 70% of stroke survivors will experience problems with bladder control (Marinkovic and Badlani, 2001). Stroke severity is closely linked with development of UI, and those with more severe stroke tend to have more severe incontinence problems. Both ischemic and hemorrhagic stroke can cause subsequent incontinence. Continued UI in those who were previously dry is a marker condition for increased morbidity and mortality after stroke (Patel et al, 2001). Stroke laterality and hemispheric dominance have generally not been found to be associated with differences in UI patterns or severity (Gupta et al, 2009; Kim et al, 2010b). However, brainstem strokes that affect the pontine micturition center tend to cause worse incontinence. DO is the predominant urodynamic finding in patients with poststroke incontinence and is typically associated with urinary urgency, frequency, and urge UI. However, some patients will experience poor detrusor contractions and chronic urinary retention with associated incontinence. Continued UI after stroke is associated with greater levels of functional dependence and higher overall care needs (Mizrahi et al, 2011). Poststroke incontinence has been linked to poorer overall QoL and alterations in sense of well-being (Tibaek et al, 2011). FI is also a common finding in patients with poststroke UI because of overlap in neural control mechanisms (Brittain et al, 2006; Kovindha et al, 2009). Interaction between cognitive and mobility impairment after stroke and associated UI and voiding dysfunction is complex. Among those with mobility impairment, decreased mobility velocity has been linked to worse LUTS severity (Tibaek et al, 2009).

The term *precipitancy* has been used to describe the symptom that occurs with DO in older adults (Resnick, 1990). In patients with no sensation of warning, precipitant leakage may be experienced as an unconscious or reflex episode of incontinence. In contrast, in those with a warning sensation, precipitancy is the abrupt sensation of imminent leakage, regardless of time interval or the amount of urine loss (Resnick, 1990).

DO may exist with or without other comorbid disease. Underlying neurologic disorders such as Parkinson disease, Alzheimer disease, multiple sclerosis, spinal stenosis, or prior stroke tend to be associated with DO and related urinary dysfunction. However, in many cases, no specific cause for DO can be identified. This makes evaluation and targeted treatment of DO in older adults more challenging.

The term *overactive bladder* is used to describe the symptom complex experienced by patients. This includes “urgency, with or without urge incontinence, usually with frequency and nocturia” (Wein and Rovner, 2002). This can be further subdivided into OAB-dry, in which patients experience urinary urgency and frequency symptoms but do not actually leak urine, and OAB-wet, in which urgency UI also occurs.

One form of bladder dysfunction that is unique in the geriatric population is detrusor hyperactivity with impaired contractility (DHIC) (Resnick and Yalla, 1987). In this condition the patient experiences DO with bladder filling, which is associated with the typical symptoms of urinary urgency, frequency, and potentially urgency UI. However, during the voiding effort the bladder does not contract efficiently or with sufficient force to completely empty. In some ways, this represents a functional combination of both OAB and underactive bladder (UAB). Brain imaging studies have shown

hypoperfusion abnormalities that localize to the frontal and global cortical areas and that are often associated with cognitive impairment (Griffiths et al, 2002). In some cases, detrusor contraction strength may actually be increased, particularly in the presence of urge UI. Monotherapy with antimuscarinic medications or other bladder relaxants can worsen urinary retention and promote development of chronic urinary retention with associated incontinence. Successful treatment often requires multimodal therapy including behavioral interventions and medications to inhibit DO and clean intermittent catheterization (CIC) to empty the bladder. Intentional induction of urinary retention with antimuscarinic medications to control hyperactivity, combined with CIC performed on a regular schedule to empty the bladder, can be a successful method for clinical management in some patients. Future research will be needed to help develop more optimal forms of management for this complex condition (Taylor and Kuchel, 2006; Smith et al, 2014b).

Stress UI is common in older people and may occur in both men and women. **In women, stress UI is usually caused by either urethral hypermobility or intrinsic sphincter deficiency (ISD).** Both pelvic floor support and urethral closure pressure tend to decrease with advancing age, and this increases risk of both urethral hypermobility and ISD in elderly women. Urethral atrophy associated with decreased tissue estrogenization and other age-related factors can exacerbate ISD and stress UI in this population. Stress UI in men is often related to prior surgical therapy for either BPH or prostate cancer. Both transurethral resection of the prostate (TURP) and radical prostatectomy have been associated with increased risk of stress UI in men. Enhancements in surgical technique and targeted therapy with pelvic floor muscle exercise (PFME) and other behavioral interventions may potentially reduce overall incidence and prevalence of postprostatectomy UI in older men (Goode et al, 2011; Mirza et al, 2011; Kojima et al, 2013).

Detrusor underactivity, sometimes called underactive bladder, can be caused by a wide variety of conditions. Often the cause is idiopathic, but recent research has led to emerging data on this condition (Griebeling, 2013a; Chancellor, 2014; Griebeling et al, 2014). Poorly controlled diabetes can lead to impairment of bladder contractility and a diabetic cystopathy. Patients can develop impairments in bladder sensation, leading to behavioral changes and a prolongation of the intervoiding interval. This cyclic but chronic bladder overdistention may be associated with subclinical bladder ischemia, which leads to progressive muscle dysfunction. Pelvic atherosclerosis is associated with diminished arterial blood flow to the bladder, which could cause ischemic changes. This in turn can promote development and release of free radicals and accumulation of oxidative stress, causing damage to cells and tissues.

Untreated chronic BOO can lead to detrusor dysfunction and chronic urinary retention in men, although this is less common with early detection and targeted interventions. Anatomic urethral obstruction in women is uncommon and most typically caused by prior urethral trauma. Large POP can cause functional obstruction with urethral kinking or angulation. Many of these women describe having to manually reduce prolapse with a finger in the vagina to void to completion. Use of a pessary or surgical prolapse repair can help treat this type of voiding dysfunction. Iatrogenic urinary retention can occur after surgical therapy for stress UI and may require surgical revision of the prior repair (Anger et al, 2007a, 2007b).

The term *functional incontinence* is sometimes used to describe urinary leakage caused primarily by factors other than the bladder itself. The ICS does not specifically define or recognize this term, but it is commonly used in research and clinical practice. **The most common factors associated with functional incontinence in geriatric patients include mobility limitations and cognitive impairments.** Care must be exercised to consider potentially reversible causes of transient UI other than restricted mobility and cognitive changes because these can coexist in patients felt to have functional incontinence. The identification of a functional component should also not presume that underlying lower urinary tract function is normal. Indeed, older adults with mobility or cognitive impairment and functional incontinence may have other underlying urologic pathology that predisposes them to UI. **Neither cognitive**

impairment nor immobility mean that UI will be an inevitable outcome. In fact, the majority of older adults with both mobility limitation and cognitive impairments are actually continent. In one study of nursing home residents, 17% with severe dementia were continent, and if they were able to transfer between the bed and a chair, half were continent (Resnick et al, 1988). It is also important to consider these functional limitations because although they may not directly cause UI, they can certainly contribute to the condition in otherwise susceptible individuals. Even multiple small improvements in various functional components can substantially improve or resolve UI and associated clinical problems.

Urinary Incontinence Risk Factors Specific to Geriatrics

Several etiologic factors for UI and other forms of voiding dysfunction are unique to older adults and deserve special consideration. **Impairments in functional status, including dependence on others for ADLs, have been closely linked to increased prevalence of UI** (Jenkins and Fultz, 2005; Huang et al, 2007; Khatutsky et al, 2013). Mobility impairment with diminished walking speed and balance may be important contributors to declines in ADL function and risk of UI (Fritel et al, 2013). Alterations in IADLs appear to have less influence on continence status compared with ADLs (Omli et al, 2013). Older adults are more likely to have multiple comorbidities that increase risk of developing UI. These include diabetes, metabolic syndrome, hypertension, and heart disease (Smith et al, 2010; Khatutsky et al, 2013). Risk factors for UI in elderly men and women can differ as a result of multiple factors including anatomic differences, prior medical and surgical history, and lifestyle variables (Tikkinen et al, 2013).

Modifiable risk factors including smoking and alcohol use have been identified as risk factors for UI in geriatric cohort studies (Hirayama et al, 2009; Ikeda et al, 2011). Obesity and overweight are also linked to risk of UI in older adults. This may be a result of increased intra-abdominal pressure and mobility impairments associated with morbid obesity. Both high body mass index (BMI) and increased waist circumference have been associated with UI in elderly patients (Byles et al, 2009; Krause et al, 2010).

Cognitive impairment, particularly after stroke or from underlying dementia, presents a substantial risk for development of UI among older adults (Hatta et al, 2011). Among geriatric patients with dementia living at home, reported prevalence of UI ranges from 1% to 38%, and those with more severe symptoms require more specialized home care services (Drennan et al, 2013). Alzheimer dementia tends to be associated with loss of short-term memory, which can impair ability of affected older adults to recognize sensations associated with a full bladder and need to void, accurately identify the toilet, and be able to adjust clothing or perform other tasks needed to maintain continence. Vascular dementia has been linked to diminished inhibitory control, which may influence continence status (Haruta et al, 2013).

CHF can cause UI for several reasons. Affected patients tend to make more atrial natriuretic peptide, which in turn leads to increased urine production. They also tend to have more problems with peripheral edema, which can increase urine output, particularly at night. **Increased CHF severity has been linked to increased UI severity in clinical studies** (Palmer et al, 2009; Chiu et al, 2012). Diuretics are frequently used in management of CHF, and these can worsen UI as a result of increased urine output. Decreased pulmonary status with reductions in functional lung capacity have been associated with worse UI (Hirayama et al, 2009). Common neurologic disorders in older adults such as Parkinson disease can cause DO and associated urge UI (Araki et al, 2000; Winge and Nielsen, 2012).

The term *aging in place* has been used to describe what is often considered an ideal paradigm in geriatrics. The goal is to help keep older adults living in their own homes as long as possible with as much independence as is feasible. Changes in ADL status including development of UI can be limiting factors in some cases. Older adults with UI and other ADL impairment may have greater needs for home health services compared with continent and more func-

tionally independent elders (Du Moulin et al, 2009). Those living in residential care facilities have also been shown to have increased UI prevalence and care needs compared with community-dwelling older adults (De Gagne et al, 2013). In settings where public health resources are limited, older adults simply may not have access to these types of services (Burti et al, 2012).

Incontinence in the Nursing Home Setting. UI is one of the most common conditions found in older adults living in nursing homes and other long-term care settings. Based on national data, reported prevalence of bladder incontinence is 46.1% for short-term nursing home residents and 75.8% for long-term care residents (Gorina et al, 2014). Similar rates have been observed in other countries, with more than 50% of nursing home residents experiencing chronic incontinence (Jerez-Roig et al, 2014). UI is often considered one of the primary factors that necessitates facility placement among older adults. Using national data, the calculated attributable fraction of nursing home admissions resulting from UI is approximately 0.10 (95% CI 0.08 to 0.13) for men and 0.06 (95% CI 0.05 to 0.09) for women (Thom et al, 1997; Morrison and Levy, 2006). However, **new-onset UI is also a common finding among nursing home residents after admission to care facilities** (Palmer et al, 1991; Ouslander et al, 1993). Efforts have helped to substantially reduce use of indwelling urinary catheters in nursing homes, and most facilities now report relatively low rates of 7.3% among long-term residents and 13.9% in short-term residents (Gorina et al, 2014). Short-term urinary catheters can be quite useful, particularly in older adults with associated clinical problems such as mobility limitation from lower extremity or pelvic fractures. However, even in these circumstances, rates of catheter-associated infections of more than 30% have been reported (Kamdar et al, 2009).

All nursing home residents undergo a comprehensive evaluation, including an assessment of urinary control and continence status, at the time of admission. Additional assessments are performed at least quarterly and more frequently if clinically indicated. Completion of the Minimum Data Set (MDS), a comprehensive multidimensional clinical assessment and documentation tool, is required for every nursing home resident in facilities that receive reimbursement from Medicare and/or Medicaid. It is completed within the first 2 weeks of admission, and at least annually. A short form is completed quarterly and in cases of substantial clinical change. Nursing homes in the United States are under strict regulatory control, and frequent inspections are required. F-Tag 315 is the national quality measure that examines UI and catheter use in nursing homes (Johnson and Ouslander, 2006). It is used to help facility surveyors assess care for UI and catheter use in long-term care facilities. In a survey study of nursing home staff and state surveyors, there were substantial differences in knowledge about UI and attitudes toward this federal regulation (DuBeau et al, 2007). Other research has shown similar variation in levels of understanding and attitudes about UI of nursing home staff (Saxer et al, 2009). **Organizational factors can be as important as clinical medicine and nursing issues in this setting** (Yoon et al, 2012). This highlights the need to include nursing home staff and administrators in quality improvement. Process change in nursing home settings can be challenging, and ongoing research seeks to improve these methods (Grabowski et al, 2014).

Catheters are usually not used for UI management in this setting. Rather, they are used for treatment of chronic urinary retention, particularly among older adults who cannot tolerate CIC because of physical or cognitive issues or in cases of significant caregiver burden (Jonsson et al, 2011b; Lin et al, 2011). **Continued use of indwelling catheters in nursing home residents is subject to intense scrutiny and must be clinically justified in each specific case** (Gammack, 2003). Management of UI and other voiding dysfunction among morbidly obese nursing home residents can be particularly problematic. These individuals often have multiple comorbid conditions, and mobility and transfers may be severely limited (Bradway et al, 2010). Catheter use may be considered in select cases.

The need for continued Foley catheter drainage among older adults discharged from acute care hospitalization has been

associated with substantially increased rates of both short-term mortality and need for institutional placement at time of discharge (Bootsma et al, 2013). However, caution must be used to balance risk and benefit. Bacterial colonization is common, with 98% of indwelling catheters among geriatric nursing home residents affected (Jonsson et al, 2011a).

Absorbent pads and products are often used as part of a “check-and-change” approach to management of UI in geriatric nursing home residents, particularly in cases where more active forms of therapy might not be feasible because of cognitive or other functional impairments. Although many nursing home residents prefer scheduled toileting and active interventions, use of pads and products can be effective in select cases (Pfisterer et al, 2007). Research has shown, however, that pad-per-day use does not necessarily correlate well with actual UI volumes or severity (Omli et al, 2010).

Urologic consultation in nursing home settings can be useful for evaluation and management of complex genitourinary conditions or to supplement ongoing therapies administered by nursing home staff (Watson et al, 2010). This can obviate the need to transport older adults from their place of residence to outpatient clinics or hospital settings. However, in the current national model of physician reimbursement, this type of on-site consultation service can be difficult to maintain over time because of administrative and cost barriers.

Targeted protocols to treat UI in long-term care settings have proven quite successful. Prompted toileting can be used with residents who have adequate mobility and cognitive function to use toilet facilities independently. Patients are prompted by caregivers or staff to use the toilet on a regular schedule. Timing is adjusted based on specific individual needs. In those older adults with mobility and/or cognitive impairment, assisted toileting procedures may be necessary. These involve having staff physically assist older adults to the toilet and guiding them through the process of adjusting clothing, using the toilet, and cleaning after voiding and/or defecation. Individually devised plans may be needed for each resident depending on his or her condition. Use of bladder scan ultrasound may be useful in this process to help identify when subjects need to use the toilet (Iwatsubo et al, 2014). The use of assistive toileting devices such as handheld urinals or bedside commodes may be necessary depending on functional status. Functional incidental training (FIT) has been used as a successful model of assisted toileting with older nursing home residents. In the FIT model, residents combine physical activity and mobility training with scheduled and assisted toileting (Schnelle et al, 1995).

Clinical Evaluation of Incontinence

Clinical evaluation of UI in older adults requires special consideration of associated health factors and can differ substantially from standard evaluation in younger and healthier patients. In particular, careful attention must be paid to potential contributions of comorbidity, either as a causative factor or an effect from UI. Evaluation should seek to identify any of the previously described reversible transient causes of incontinence. It should also assess caregiver and social support and the environmental setting where the older adult resides. The evaluation could also identify other serious urologic conditions that can be associated with UI including bladder cancer, benign or malignant prostate disease, neurologic disorders, or stone disease.

Additional details about the evaluation of UI in geriatric patients including history, physical examination, assessment of postvoid residual (PVR) volume, voiding diaries, laboratory testing, and urodynamic studies can be found on the Expert Consult website.

Treatment of Incontinence

Treatment of UI must be carefully tailored to the individual patient. This is particularly true among geriatric patients because there can be substantial heterogeneity among individuals based on comorbidities, functional status, and goals of care. Because causes of established UI in geriatric patients are multifactorial, treatment

also frequently requires multiple components and approaches. **In many cases the actual target of therapy may be outside of the lower urinary tract to address contributions from comorbidities and other contributing clinical conditions.** Behavioral therapies are a mainstay of treatment of UI in geriatrics, although medications and surgeries can also be used successfully in this population.

Additional information regarding specific geriatric considerations for treatment of incontinence with behavioral therapies, pharmacotherapies, and surgeries, including bulking agents, sling procedures, artificial urinary sphincter (AUS) placement, neuromodulation, chemodenervation, urinary diversion and indwelling urethral or suprapubic catheters, and use of urine containment and absorbent products, is included on the Expert Consult website.

Other Lower Urinary Tract Dysfunction, Pelvic Floor Conditions, and Genitourinary Trauma

A wide variety of other lower urinary tract and pelvic floor conditions can affect older adults and require special considerations for geriatric patients.

Details on BOO, UAB and urinary retention, nocturia, FI, continence promotion and advocacy, POP, UTIs and asymptomatic bacteriuria, hematuria, and genitourinary trauma are included on the Expert Consult website.

Genitourinary Malignancies

Almost all of the genitourinary cancers occur with greater incidence and prevalence in geriatric patients than in their younger counterparts. The one exception is testis cancer, wherein lymphoma is the most common histology seen in geriatric men.

Detailed information on specific geriatric considerations for Prostate cancer, bladder cancer, kidney cancer, and testis cancer are included on the Expert Consult website.

Sexual Health in Elderly Women and Men

Sexual health is an important part of life for most adults, even at advanced age. **Many older adults wish to remain sexually active throughout their life (Hyde et al, 2010).** Data from the National Survey of Sexual Health and Behavior (NSSHB) in 2009 demonstrated that 20% to 30% of all older adult men and women remained sexually active well into their 80s (Schick et al, 2010). **A common myth is that older adults are not able or interested in participating in sexual activity.** Forms of sexual expression may change with time over the life span (Lindau et al, 2007). Lack of a partner is a limiting factor for many older adults. Penetrative sexual activity may become less important for some older adults, and there may be an increased emphasis on intimacy and other types of erotic interaction. Masturbation may become an important form of sexual expression for many older adults.

Comorbidity plays an important role in sexual health for many older adults. Those with better overall health tend to be more sexually active than those with poorer functional health status (Lindau and Gavrilova, 2010; Bach et al, 2013). **Changes in sexual health may be a sign or symptom of underlying systemic disorders.** Multiple studies have linked obesity, diabetes, cardiovascular disease, and neurologic disorders such as Parkinson disease and stroke to erectile dysfunction in elderly men (Marinkovic and Badlani, 2001; Seftel, 2003; Riedner et al, 2006; Justo et al, 2010; Garimella et al, 2013). Alterations in sex hormones and testis function have been shown to influence erectile function and cardiovascular health in elderly men (Rastrelli et al, 2013). UI and other LUTS can negatively influence sexual health for many older adults (Griebing, 2006; Tannenbaum et al, 2006). Frailty affects multiple physical and psychosocial domains and has been shown to be linked to worse sexual health status (Lee et al, 2013a). Other physical health issues may influence the ability to engage in sexual activity. Severe arthritis may make some positions for intercourse painful or impossible. Atrophic vaginitis can cause dyspareunia in

Evaluation should be individually tailored to the clinical needs and goals of the patient and his or her caregivers. In some cases, complete resolution of UI may not be feasible, but even small improvements in the condition can yield substantial functional results. For example, improvement in volume or frequency of urinary leaking may allow someone who was previously confined to the home the ability to get out and interact in social settings more easily. Simple interventions can sometime have substantial positive effects. In most clinical guidelines, these form the cornerstone of initial therapies. However, a comprehensive approach is often the most effective when addressing the complex topic of UI in older adults.

History. A detailed history is essential to proper diagnosis and selection of therapy for UI in older adults. The characteristics of incontinence including duration, frequency, and volume should be determined. Any exacerbating factors such as physical activity, coughing, laughing, sneezing, or other factors should be assessed. A review of medical records can be extremely valuable. This would include any prior treatments that have been attempted and prior surgical records if available. Some patients will be unable to provide their own historical information, and portions of or in some cases the entire history may need to be obtained from caregivers or surrogates. A telephone call to the patient's geriatrician or primary care provider can be quite valuable for obtaining historical information. For those older adults who reside in long-term care facilities, a call to the nursing staff member most familiar with the patient can help put clinical questions into better context. This can also help clarify goals of evaluation and treatment.

In some cases, a careful history will allow the clinician to determine the type(s) of UI a given patient experiences. However, this is not always true, particularly for elderly patients who may have more complex voiding dysfunction. The symptom of urinary urgency is extremely common but is neither particularly sensitive nor specific for DO. This may or may not be accompanied by actual urinary leakage. Similarly, urinary frequency is a common complaint that must be placed in clinical context. This may be caused by true DO, sensory changes that result in frequency of urination, or incomplete urination leading to rapid refilling of the bladder. In some cases this is a learned behavior or purposeful technique to avoid UI that might occur near bladder capacity. Voiding diaries can be helpful in gaining more insight into these clinical complaints.

Identifying the most bothersome component or characteristics of UI is particularly important in older adults. This can help to target treatments that can yield clinically meaningful improvements even if urinary leakage cannot be completely eliminated and is one of the main components of patient-centered therapy.

Physical Examination. The physical examination is a crucial part of overall assessment of older adults with UI. In addition to routine aspects of physical examination including pelvic examination in women and genital and rectal examination in men, several unique components are also included for older adults with incontinence. The general physical examination should include identification of conditions associated with fluid overload and associated incontinence including peripheral edema, CHF, and pulmonary edema.

Neurologic examination includes gait and balance, mobility, and ability to transfer between positions. This includes ability to get on and off a chair, which can be similar to getting on and off the toilet. Clinical signs associated with common rheumatologic and neurologic disorders in older adults should also be evaluated. These include changes from arthritis and joint disorders, Parkinson disease, multiple sclerosis, prior stroke, spinal stenosis, cord compression, vertebral disk herniation, acute or chronic back pain, dementia, and delirium.

Perineal sensation should be tested, and may be diminished or asymmetric, particularly in those with a history of underlying neurologic disease. For example, patients with a history of stroke and associated hemiparesis may have asymmetric perineal sensation. Tissue quality should be assessed including presence or lack of rugation of the vaginal mucosa. Atrophic vaginitis is common in postmenopausal women and is usually caused by lack of estrogen.

This can also lead to fusion or "agglutination" of the labia minora or labia majora. In some cases this can cause voiding dysfunction and BOO (Chang et al, 2012a). Vaginal narrowing or stenosis is another common finding on pelvic examination in elderly women. This is sometimes associated with a prior history of pelvic radiation therapy.

Pelvic examination in women should be performed with the bladder moderately full to evaluate for stress UI. Many older women wish to void before pelvic examination because it makes this more comfortable, and they may be used to doing so before routine gynecologic examinations. In some cases, women want to void before examination to avoid potential embarrassment with urine leakage in front of the clinician. However, if the patient voids to completion before the examination, determination of stress leakage with cough or Valsalva will be severely limited. Gentle reassurance of the importance of doing the examination with urine in the bladder and objective identification of stress leakage can be very useful and can help put the patient at ease.

Rectal examination may reveal signs associated with chronic constipation or fecal impaction. The bulbocavernosus reflex may be absent in older adults, although this change may or may not be associated with underlying neurologic pathology. Prostate enlargement or nodularity may be palpable, although prostate size on rectal examination does not necessarily correlate with symptoms. Rectal cancers are more common among older adults, and the majority of lesions are palpable on digital rectal examination. Stool guaiac testing should also be considered and can help to identify otherwise silent pathology in some patients (Goetzl et al, 2008).

Having the patient void as part of the physical examination can be particularly useful in geriatric patients. This may include actually taking the patient to the toilet to observe his or her behaviors and level of need for assistance. Is the patient able to recognize the toilet? Is he or she able to identify the sensations provided by a full bladder and respond appropriately to these signals? Is the patient able to adjust clothing independently to allow use of the toilet? This can provide insight into potential issues of cognitive or physical functional impairment that could change the course of recommended therapy.

Assessment of Postvoid Residual Volume. Many older adults do not completely empty the bladder with voiding. Elevation of the PVR volume is common in older adults. However, no specific volume is considered pathologic and there is a great deal of controversy surrounding the importance of elevated PVR volume in older adult patients. (Huang et al, 2011; Shimoni et al, 2015).

Measurement of PVR volume can be accomplished with either ultrasound scan or bladder catheterization. Ultrasound is convenient and eliminates the need for urethral instrumentation. However, the device is expensive and not all clinics will have this equipment available. Some nursing homes, outpatient clinics, emergency rooms, and other facilities that provide care for older adults have invested in this type of technology (Omli et al, 2008).

Measurement should ideally be completed immediately after a voluntary void rather than after an incontinent episode. However, in some patients, particularly those with cognitive impairment, this may not be feasible. Measurement of PVR volume after an incontinent leakage episode can be useful, particularly if the volume is low because this indicates complete bladder evacuation.

Voiding Diaries. The use of voiding diaries can be particularly helpful in assessing UI and other forms of voiding dysfunction in older adults. They can help identify patterns of voiding in terms of time and associated factors. This can be useful to differentiate the type of UI in some cases. It can also be helpful in identifying cases of daytime or nocturnal polyuria. Research has shown that diaries completed over 3 days can be valid for analysis, and this eliminates need for extended 7-day or longer diaries (Dmochowski et al, 2005). Most diaries are completed using paper forms, although electronic diaries are also available and are frequently used in clinical research trials. If clinicians are going to use voiding diaries with older adult patients, care should be used to make sure the font is large and easily readable and that adequate instructions are provided for proper completion.

Findings from the voiding diary can be very useful in helping to guide treatment for UI in older adults. The voiding diary can help identify voiding patterns and provides an objective tool to validate subjective symptoms. It can be particularly helpful in patients with nocturia to differentiate nocturnal polyuria from some of the other causes of the condition (Weiss and Blaivas, 2000; Udo et al, 2009). In some cases, recording fluid intake may be useful, but this increases the complexity of the data the older adult is asked to collect. Information on fluid intake is particularly useful to identify polydipsia or fluid restriction, which could be causing voiding problems.

Laboratory Testing. Geriatric patients need some special considerations for laboratory testing related to urologic health. Urinalysis and urine cultures should be obtained when clinically indicated and can help to identify underlying comorbidity. **The American Urological Association (AUA) guidelines recommend checking a urinalysis as part of the initial evaluation for UI** (Dmochowski et al, 2010; Gormley et al, 2012). Gross or persistent microhematuria warrants additional evaluation, including in older adults who are on anticoagulation therapy (Davis et al, 2012). Urine cultures are important to help diagnose the cause of UTIs and guide therapeutic choices. Persistent sterile pyuria should raise suspicion for possible genitourinary tuberculosis in older adults, who can harbor this infection without other signs or symptoms (Kulchavenya et al, 2013).

Measurement of serum creatinine alone frequently does not adequately reflect true renal function in geriatric patients. This is because of natural loss of muscle mass with aging, which influences observed serum creatinine levels. Several options have been developed to correct for this measurement disparity (Aucella et al, 2010). A 24-hour urine collection will provide the most accurate information but may be difficult to obtain for many patients, particularly those with substantial UI. The most commonly used estimation equations include the Cockcroft-Gault and Modification of Diet in Renal Disease (MDRD) models. Correction factors for age and body habitus can help improve accuracy of these estimates of GFR (Schaeffner et al, 2012; Van Pottelbergh et al, 2014; Zhu et al, 2014).

Serum electrolytes should be checked in patients with delirium because this can be a causative and potentially reversible factor in some cases. Glucose measurement is useful in diagnosing underlying diabetes, which could be associated with renal, lower urinary tract, and sexual health disorders.

Urodynamic Studies. Urodynamic studies can be useful in the evaluation of select elderly patients with UI and other forms of voiding dysfunction (Diokno, 1990). The AUA has published guidelines regarding the use of urodynamic studies for assessment of voiding dysfunction (Winters et al, 2012). **Primary indications for urodynamic studies, particularly in older adults, include failed prior therapy, underlying neurologic or other comorbid conditions that could influence voiding function, and planned genitourinary reconstruction.** It is important to consider if and how findings from urodynamic testing might change treatments. If different urodynamic results would not alter therapy, then testing would not be warranted. However, if different treatment options would be considered based on the observed results from the testing, then it would be justified. Pressure-flow urodynamic testing can be particularly helpful to differentiate between functional obstruction and UAB with poor contractility and incomplete bladder emptying.

Several factors must be specifically considered for geriatric patients who may undergo urodynamic testing. Although minimally invasive, the study is in some ways an interventional procedure and must be conducted in this context. The test is quite interactive, and patients need to be able to follow directions and describe what they are feeling at various points. They need to be able to be positioned adequately and undergo catheter placement. Older adults with cognitive or mobility limitations may have difficulty participating in urodynamic testing, which could compromise the quality of the findings. **Ideally, the symptoms being targeted for analysis and treatment should be reproduced during urodynamic testing.** This can be difficult to achieve in the urodynamic laboratory, but a variety of techniques can be used to help with standardization of methodology. The importance of good urodynamic technique and testing quality cannot be overemphasized (Schäfer et al, 2002). Most urodynamic testing is conducted in hospital or clinic-based facilities, although portable and ambulatory urodynamic evaluation can be performed in select cases. The role of urodynamic testing in the nursing home and other care settings is relatively limited and should be reserved for specific cases where results of the testing would substantially influence treatment considerations. Staffing and reimbursement may also be a limiting factor for studies done in mobile settings such as nursing homes.

In a large cohort study of urodynamic findings in 100 community-dwelling elderly women, the most common clinical conditions identified include DO and DHIC (Valentini et al, 2010). These tended to be strongly correlated with patient symptoms. However, other studies have contradicted this finding and suggest that in some older adults the observed correlation between clinical symptoms and urodynamic findings may be lower (Bromage et al, 2010). This likely reflects alterations in anatomy or physiology and overall heterogeneity of changes seen with advancing age among older adults.

Behavioral Therapies. Behavioral therapies are considered the mainstay of therapy for treatment of UI in older adults. They offer the advantage of good clinical efficacy while avoiding potential side effects often associated with medications or surgery.

Some older adults choose to limit fluid intake in an attempt to reduce urge incontinence or urinary urgency or frequency episodes (Miller et al, 2011; Segal et al, 2011). Although this can be useful in select cases, particularly at night in those with symptomatic nocturia, care must be taken to avoid dehydration. **Reduced fluid consumption can exacerbate both UI and constipation.** In addition, restriction of fluids can lead to production of a stronger and more concentrated urine, which is actually more irritating to the epithelium. Although total urine volume is reduced, increased urinary concentration can actually worsen urge symptoms. Other common dietary recommendations include avoidance of foods or beverages that tend to trigger urinary urgency and frequency symptoms. These include caffeine, carbonated beverages, alcohol, and spicy or acidic foods (Gleason et al, 2013).

Timed or scheduled toileting can be quite useful in some patients with urinary urgency and frequency. Many older adults have worse symptoms near bladder capacity. **Voiding on a more regular schedule before reaching capacity may help to limit urge sensations and associated leaking.** Bladder retraining, a series of steps to increase the intervoiding interval, can also be useful in select cases. This can help to slowly increase functional bladder capacity and response to sensations of bladder filling. One clinical trial demonstrated a mean reduction of 57% for urge incontinence frequency in elderly women (Fantl et al, 1991). Delayed voiding is similar except that patients do not follow a predetermined time interval, but instead base their schedule on sensations as they experience them (Burgio et al, 2011). Biofeedback training is sometime used in combination with this type of intervention (Newman, 2014). Urge suppression methods are frequently combined with other types of therapy as a form of habit retraining to improve UI symptoms (Ostaszewicz et al, 2004).

PFME is one of the primary forms of behavioral therapy used to treat UI in older adults. Numerous studies have shown that both men and women with various types of UI can benefit. However, simply telling people to do Kegel or pelvic muscle exercises is unlikely to be successful. **Most older adults require specific training for these methods to work.** Cognitive impairment may limit practicality of this therapy in some patients. It requires a motivated patient who is willing to do the exercises and is able to follow guided instruction. In a study of hospitalized older women (mean age 78.2 ± 6.3 years), the vast majority (74.5%) were unable to voluntarily contract their pelvic floor muscles (Talaszi et al, 2012). With proper instruction, PFME has been shown to improve UI more than just bladder training and timed voiding alone (Sherburn et al, 2011). PFME is often used in combination with other forms of behavioral or pharmacologic therapies, and effects may be additive or synergistic (Burgio et al, 2000; Ghoniem et al, 2005). In some cases, patients may be able to decrease or discontinue medications for UI, depending on success of PFME and behavioral treatments (Burgio et al, 2008). It has also been shown to be effective in men with a history of postprostatectomy incontinence and in patients with symptomatic nocturia (Johnson et al, 2005; Goode et al, 2011).

PFME appears to have a direct effect on pelvic anatomy and physiology. It has been shown to improve both pelvic floor muscle morphology and dynamic function over time (Dumoulin et al, 2007; Madill et al, 2013). A variety of teaching methods have been developed and advocated for PFME instruction in older adults. These have been used successfully in nursing home settings (Engel et al, 1990; Vinsnes et al, 2012). Group instruction is feasible and has been shown to have good outcomes (Sampselle et al, 2005; Lajiness et al, 2007). This may be particularly useful for older adult patients, who may benefit not only from direct instruction but also from interaction and support of the group learning PFME together. It may also be a more efficient and cost-effective way to disseminate this type of clinical education for multiple patients. This was shown to be effective in a nursing home setting where participants also experienced improvements in overall functional status (Tak et al,

2012). Online instruction with Internet-based teaching and interactive support forums has been shown to be successful in early trials (Sjöström et al, 2013).

Vaginal cones can be used to augment pelvic floor exercise and may help patients to identify the muscles used in this technique. However, randomized controlled trials have not shown statistically significant differences in continence outcomes with or without cones (Pereira et al, 2012, 2013). Electrical stimulation of pelvic floor muscles can also be used, but results of this treatment compared with PFMEs alone have been mixed (Castro et al, 2008; Correia et al, 2014). Weight loss has been shown to be effective at improving stress UI and FI in elderly women with obesity (Subak et al, 2009; Markland et al, 2011).

Pharmacotherapies. Medications are widely used in treatment of UI. The specific drug selected is typically based on the type and cause of UI experienced by the patient. Unfortunately, there are currently no pharmacologic agents available in the United States that are particularly effective for treatment of stress UI in older adults. Medications with α -agonist properties such as pseudoephedrine have been tried but tend to have substantial side effects and limited clinical efficacy in geriatric patients. The older medication phenylpropanolamine was removed from the market by the U.S. Food and Drug Administration (FDA) because of increased risk of serious side effects including hemorrhagic stroke and other thromboembolic events (Meadows, 2001). Duloxetine, a balanced serotonin and noradrenaline reuptake inhibitor, also has α -adrenergic properties and has been considered as a possible treatment option for stress UI (Basu and Duckett, 2009). Although it is used in some parts of the world, it is not approved by the FDA for this purpose.

The majority of medications have been designed to treat OAB including urinary urgency, frequency, and urge UI. These are mostly antimuscarinic, anticholinergic medications that act by blocking muscarinic receptors in the bladder which in turn decreases detrusor contractions. The classic medication in this group is oxybutynin. Although it can be quite effective for management of bladder symptoms, it has strong anticholinergic properties that can cause problematic side effects in older adults. The most common include dry mouth and constipation, although dry eye, headache, confusion, and other anticholinergic effects may also occur (Pagoria et al, 2011; Moga et al, 2013). A variety of newer anticholinergic medications have been developed with the goal of reducing DO and associated OAB symptoms but minimizing potential side effects. These medications can be used in men and women, and all have been shown to have relatively similar efficacy (Madhuvrata et al, 2012).

Several of the newer medications have theoretic advantages for use in older adults. In some cases these may have a real physiologic effect, but to some extent the primary purpose has been differentiation in marketing for various drugs. Differences among medications have been based on a variety of factors including lipophilicity, molecular size, selective affinity for various muscarinic receptor subtypes, drug half-life, and other metabolic effects. For example, trospium is a quaternary amine, unlike the other agents, which are tertiary amines. Animal studies have shown that trospium may be less likely to cross the blood-brain barrier, which may therefore decrease the potential cognitive side effects from this medication (Kranz et al, 2013). However, changes in the blood-brain barrier with aging increase permeability and may alter drug efflux in older adults (Chancellor et al, 2012). Studies of these types of medications in older adults need to examine cognitive side effects (Kay et al, 2006; Paquette et al, 2011). Improved selectivity of muscarinic receptor binding is another focus in drug development. The goal is to target the bladder (M_2 and M_3) but avoid the salivary gland and bowel (both M_3), which may help reduce the risk of dry mouth and constipation (Abrams and Andersson, 2007).

The route of administration and type of drug delivery system are also important considerations for several of these medications. These can influence pharmacokinetics and pharmacodynamics of these preparations. Immediate-release drugs offer quick onset of action, but long-acting or timed-release agents may have a benefit of a more stable steady state of circulating medication. Transdermal preparations avoid the first pass effect through the liver and may be

useful in patients with hepatic insufficiency. They are also useful in patients with swallowing difficulties that can prevent effective use of oral tablet or capsule formulations. Liquid oxybutynin is available and can be administered through feeding or gastric tubes in patients unable to swallow liquids or other formulations.

One of the challenges is that older adults are frequently excluded from clinical trials used to approve medications and other treatments because of their underlying comorbidity and heterogeneity (Briggs et al, 2012; Beers et al, 2014). However, the reality is that these drugs are widely prescribed in this patient population in routine clinical practice (Kraus et al, 2010). This means that potential side effects and interactions among medications and underlying comorbidity have been studied in less detail, which makes clinical decisions and prediction of outcomes more difficult. Several studies have examined use of antimuscarinic medications specifically in older adult cohorts. Fesoterodine was demonstrated to have good clinical efficacy in a 12-week randomized, placebo-controlled trial in a group of 562 elderly patients with a mean age of 75, and with 50.4% of patients being 75 years of age or older (DuBeau et al, 2014). This group had high baseline rates of comorbidity, polypharmacy, and functional impairment, which mirrors real-world prescribing challenges. The medication was well tolerated in general, and overall adverse event rates were similar to those seen in younger patient populations. These results were also demonstrated in a similar trial of fesoterodine conducted with geriatric patients in Europe (Wagg et al, 2014b). Studies on older adults have also shown relatively good efficacy and tolerability for tolterodine, solifenacin, darifenacin, and trospium (Lipton et al, 2005; Wagg et al, 2006; Chapple et al, 2007; Griebeling et al, 2009; Sand et al, 2011; Wagg et al, 2013a). One study of fixed low-dose, extended-release oxybutynin in cognitively impaired older adults living in nursing homes did not seem to worsen cognition and decreased the number of wet pad checks by 38%, but failed to show a significant benefit for UI overall (Lackner et al, 2011). An earlier study had also shown relatively good tolerability with no increase in rates of delirium in a cohort of cognitively impaired nursing home residents (Lackner et al, 2008).

Most of these medications undergo either hepatic or renal metabolism, and care needs to be used in patients with liver or kidney impairment. Use of the lowest clinically effective dose is usually recommended. Drug-drug interactions tend to occur with other drugs that undergo hepatic metabolism. Drug-food interactions have also been identified, particularly with alcohol and grapefruit, which can lead to inhibition of the cytochrome P450 pathway. **Use of the antimuscarinic and anticholinergic medications is also contraindicated in patients with closed-angle (narrow) glaucoma.** Consultation with a patient's ophthalmologist or optometrist may be needed in these cases before prescribing these medications. Open-angle glaucoma is much more common, and this by itself is not a contraindication to use of the antimuscarinic anticholinergic medications for treatment of urinary symptoms.

Adverse effects of antimuscarinic medications are one of the primary limiting factors for ongoing use, particularly among older adults (Sears et al, 2010; Wagg et al, 2012). Discontinuation of medication is common, and several different medications may need to be tried to find one that is acceptable for an individual patient. Urinary retention is a theoretic risk with all of these medications, although this is not commonly seen in clinical practice. Monitoring of PVR volumes after initiation of therapy might be considered.

A new class of agents for treatment of OAB is the β_3 -adrenoceptor agonists. Mirabegron is the only agent in this class currently approved in the United States and is available in 25-mg and 50-mg doses taken once daily. This acts on detrusor smooth muscle to decrease contractility and reduce symptoms associated with overactivity. Studies in older adults have demonstrated good clinical efficacy with relatively few side effects (Wagg et al, 2014a). This class of medications offers the potential advantage of reducing bladder symptoms without the risk of anticholinergic side effects.

Regimen compliance and continuation can be problematic with the antimuscarinic medications, particularly among older adults. Discontinuation rates are relatively high, ranging up to 50% to 86%

at 1 year (Wagg et al, 2012; Mauseth et al, 2013; Sicras-Mainar et al, 2014). Although all of the available medications have been shown to be effective in clinical trials, the response of an individual patient to a specific medication is difficult if not impossible to predict. Patient perception of the degree of improvement is very important in the patient's decision to continue or stop pharmacotherapy (Basra et al, 2008). Older adults frequently discontinue these types of medications because of either lack of perceived efficacy or development of adverse effects such as dry mouth, constipation, or confusion.

Cost is also an important consideration when using pharmacotherapy for UI in older adults (Perimenis et al, 2006; Armstrong et al, 2012). Many geriatric patients are on a fixed income, and they may or may not have insurance coverage for prescription medications. Coverage varies widely among different policies and different drugs. Even under the Medicare Part D benefit, older adults may have a substantial out-of-pocket expense, particularly if they are on multiple medications and have used the extent of their available benefits. Different medications may have different preferred formulary status with different coverage plans. Patients often need help navigating these complexities with their insurance providers and pharmacies.

Use of antimuscarinic medications in patients with underlying cognitive impairment or dual use in those on cholinesterase inhibitors requires special consideration. These drugs theoretically act in pharmacologic opposition and may influence symptoms of the other disease process. There have been anecdotal reports of patients developing UI after initiation of a cholinesterase inhibitor, and, conversely, cognitive decline has been reported in some patients after initiation of an anticholinergic medication for treatment of urinary symptoms (Hashimoto et al, 2000; Siegler and Reidenberg, 2004; Starr, 2007). This can be associated with an increased risk of polypharmacy in these older adults (Modi et al, 2009). In fact, initiation of one medication may lead to symptoms that prompt subsequent prescription of the other class of medications, an example of the prescribing cascade (Jonnell and Fastbom, 2008; Boudreau et al, 2011). Larger observational studies have shown that combined use of these medications can lead to progressive cognitive decline in some older adults (Sink et al, 2008). In these cases, it can be helpful to consult directly with the treating geriatrician or neurologist to determine which medication should take priority based on the overall clinical situation. Risks and benefits of medications must be balanced with observed outcomes with regard to both urologic and neurocognitive function. Risks of cognitive change or confusion with anticholinergic medications are real, although overall reported incidence is relatively small. Discontinuation of medication usually results in resolution of the cognitive side effects.

Potential cardiac risks are also a consideration with specific antimuscarinic agents. For example, high doses of tolterodine may cause QT prolongation, which can lead to symptomatic bradycardia and even torsades de pointes. The maximum dose for specific medications should be carefully considered and should not be exceeded (Rosa et al, 2013). Anticholinergic medications also have a potential risk of inducing tachycardia, although this has not been reported as a common clinical adverse event of currently available medications. The β_3 -adrenoceptor agonist mirabegron has been associated with slight increases in blood pressure and should be used carefully in older adults with a history of hypertension (Sanford, 2013). Underlying cardiovascular disease plays an important role in these cases and should be considered when prescribing medications for treatment of OAB.

Surgical Therapies. A number of different forms of surgical therapy are used for treatment of UI in older adults. These include surgical procedures for both stress and urge UI. Many older adults want to avoid surgery as a possible treatment option for UI, POP, or other urologic conditions. Similarly, many clinicians may not consider surgical options for geriatric patients because of concerns about potential risks and complications related to age (Griebeling, 2011). However, there is a growing body of evidence that indicates surgery may be safe and effective for carefully selected older adults with UI and other genitourinary disorders. Age alone is

rarely a significant risk factor for postoperative outcomes, which tend to be more closely related to comorbidity and functional status. In fact, considering surgery earlier in the treatment algorithm may be appropriate in some cases. For example, prolapse repair performed earlier after menopause in older women has been shown to have improved outcomes compared with surgery that is substantially delayed (Ahn et al, 2010). Development of newer, less invasive effective surgical procedures has made some surgical options more viable for use in elderly patients (Atiemo et al, 2006). In addition, efforts to better optimize older adults medically before surgery may help to improve outcomes (Chow et al, 2012).

Bulking agent injections have been used to treat stress UI in older women (Lightner et al, 2002; Keegan et al, 2007). They offer the advantage of a minimally invasive technique with relatively good success rates. However, overall success is somewhat more limited compared with other surgical techniques owing to longevity of the effect and need to repeat the procedure. Conversely, the ability to repeat treatment can also be seen as a clinical advantage to bulking agent injections. A variety of materials have been used for this purpose including cross-linked bovine collagen, synthetic gels, and microbeads (Khullar et al, 1997; Winters et al, 2000; Lightner et al, 2001; Vecchioli-Scaldazza et al, 2014). **Bulking agent injection therapy may be particularly appealing in elderly women with stress UI who may not be candidates for more involved surgical therapy.** The use of bulking agents in men has shown substantially less overall success compared with efficacy in women (Griebing et al, 1997).

Sling procedures are used for treatment of stress UI. Slings for treatment in women include both pubovaginal and midurethral procedures. Various graft materials have been used for this purpose including autologous fascial grafts, other biologic grafts using either cadaveric fascia or xenografts, and synthetic mesh. Slings have also been developed for treatment of stress UI in men. A number of published studies have examined safety and efficacy of sling procedures for treatment of stress UI in geriatric patients. These have shown good outcomes in general, with no significant difference in complication rates compared with younger patients (Stav et al, 2010; Jun et al, 2012; Serati et al, 2013). However, other clinical reports suggest older women may be at increased risk for perioperative UTIs and other complications (Groutz et al, 2011). Continence outcomes may also differ, with one study reporting inferior rates of improvement in elderly women compared with younger patients after midurethral mesh sling (Kim et al, 2011a). In this study, elderly women had higher rates of parity, hysterectomy, and prior anti-incontinence or prolapse surgery. This could have influenced observed results. An analysis of Medicare beneficiary data demonstrated that elderly women appear to have a higher risk of urinary retention, urinary urgency, and other complications after sling surgery compared with younger women (Anger et al, 2007a, 2007b). Some surgeons may avoid using mesh specifically in elderly women because of potentially increased risks of erosion or other complications after this type of surgery (Reynolds et al, 2013).

AUS implantation is often used for treatment of stress UI in men. AUS devices are not commonly used in women any longer owing to advances in sling procedures, bulking agent injections, and other minimally invasive surgical options. Cognitive status and manual dexterity must be carefully considered in elderly men being considered for AUS placement because they will need to operate the device several times daily to effectively manage incontinence and void. In select patients this therapy can be quite effective (O'Connor et al, 2007). Sling procedures for treatment of UI in men have been developed, but to date there are no clinical data examining outcomes specifically in geriatric patients.

Neuromodulation uses electrical stimulation of the nerves that control detrusor contractility to treat voiding dysfunction. Two forms of neuromodulation are currently available: sacral neuromodulation with implantable electrodes (InterStim, Medtronic), and peripheral tibial nerve stimulation (Urgent PC, Uroplasty). Both have shown good success in research trials and clinical practice. Studies on use of these therapies in geriatric patients have been somewhat limited; however, reported results are promising (White

et al, 2009; Schreiner et al, 2010; Griebing, 2010). Success rates up to 83.3% at 1 year have been reported in geriatric patients who went on to generator placement (Angioli et al, 2013). Reported complication rates are quite low, even in elderly patients with multiple comorbidities (Chughtai et al, 2015). Age by itself does not appear to substantially influence overall success of therapy (Peters et al, 2013). Posterior tibial nerve stimulation has been used successfully for older adults in a residential care setting, and in patients with a history of voiding dysfunction related to prior stroke (Booth et al, 2013; Monteiro et al, 2014). Successful use of neuromodulation therapy requires that the patient be able to identify characteristics of his or her symptoms and participate in ongoing programming and adjustment of the device as needed. In some cases, if the patient is unable to do this himself or herself, assistance from a caregiver may be required.

Chemodenervation of the detrusor muscle is used to treat urinary urgency, frequency, and urgency UI. This has typically been reserved for use in cases that are refractory to other forms of therapy including behavioral or pharmacologic interventions. The most commonly used agent for this purpose is onabotulinumtoxinA. Studies in older adults have been relatively limited but have shown clinical efficacy and overall safety (White et al, 2008). The major concern of this particular therapy is the risk of urinary retention, which could necessitate CIC or indwelling catheter drainage at least temporarily.

Urinary diversion is another possible option for treatment of intractable UI in highly selected older adults. In some elderly patients, use of a urinary conduit with management of a stomal appliance is preferable to UI. **Care must be taken to evaluate potential risks of surgery and to balance this with the potential benefits of independent urinary control provided by urinary diversion (Osborn et al, 2014).** In select patients, creation of a continent catheterizable diversion may also be an option (Gowda et al, 2008).

Use of indwelling catheters is usually avoided in older adults because of the associated risks of UTI, catheter colonization, urinary tract stones, or tissue erosion (Ouslander et al, 1987; Drinka, 2006; Leuck et al, 2012). Chronic use of indwelling catheters after discharge from acute hospitalization in older adults has been linked to negative outcomes including an increased risk of mortality (Holroyd-Leduc et al, 2007). Catheters should be removed as soon as feasible to help prevent these negative outcomes. Indwelling catheters are also not particularly helpful in management of DO because they tend to exacerbate bladder contractions and can make symptoms worse. They should also be avoided for simple convenience or fluid monitoring in most patients in acute care settings.

However, use of indwelling catheters can be useful in highly select cases. These include patients with chronic urinary retention and incomplete bladder emptying who are unable to undergo CIC for various reasons. Other examples include those with morbid obesity, severe extremity contractures, or other body habitus changes that prevent catheterization. Older adults with dementia or severe cognitive impairment, severe urethral stricture disease not amenable to surgical correction, or other anatomic changes may not tolerate CIC. In such patients, use of an indwelling catheter may be more appropriate. Patients with sacral pressure ulcers or other skin breakdown may also benefit from temporary indwelling catheter drainage to keep the affected area dry and allow for tissue healing. Temporary urinary catheter drainage can also be useful after flap placement or other reconstructive surgery to keep the surgical site dry during the healing process.

When chronic catheterization is necessary, placement of a suprapubic catheter is usually preferred over urethral catheterization. This helps prevent bladder neck erosion and urethritis in all patients, and decreases rates of epididymitis and prostatitis in men. Once the tract is healed, the suprapubic tube may be easier for staff to change and may also be more comfortable for the patient. This also positions the catheter out of the urethra and genital tract and allows patients to be sexually active if so desired. The catheter should be changed at least monthly or more often if necessary based on individual clinical variables (Wilde et al, 2013). In general, cystoscopy

is recommended on at least an annual basis, particularly after the first several years of use, to evaluate for any mucosal changes such as squamous metaplasia or development of stones. If patients have problems with urinary leakage around the catheter or from the urethra, treatment should be focused on reducing bladder contractions with antimuscarinic or other agents, and assuring adequate catheter drainage. It is strongly recommended that providers *not* increase the caliber of the tube. Increasing the diameter of the catheter will not solve the underlying cause of the urinary leakage and will serve only to dilate the suprapubic tract or urethra. This can lead to severe problems with erosion and catheter extrusion. Catheters of 16 or 18 Fr are typically adequate for use as a suprapubic tube.

Urine Containment and Absorbent Products. A variety of devices and products are available to help manage urinary leakage. Although these should not be considered a curative treatment option, they can be quite useful for management of symptomatic urine loss. In some cases, use of these types of products can allow affected individuals the opportunity to participate in social activities they would otherwise avoid because of embarrassment or other factors associated with UI.

Absorbent pads and products come in a wide array of designs. These range from small pads to extra absorbent briefs and can be used for both light and heavier volumes of urinary leakage (Fader et al, 2007, 2008). There are some differences in products available for men and women with designs specific for leakage target zones based on anatomy. Advances in technology have continued to improve products including better management of odor and absorbency (White, 2003). Gel-based products may offer better odor control and have good overall absorbency, although they may not be able to control large volume leakage as well as products using wood pulp or fiber. Pads may be particularly effective in helping to reduce associated dermatologic complications such as urea derma-

titis of the perineum (Sugama et al, 2012). Pads and absorbent products are frequently used in the UI management scheme of nursing home residents and can be a useful adjunct in this setting (Pfisterer et al, 2007). Use in acute care settings should be relatively limited if possible and has been shown to potentially increase rates of UI (Zisberg et al, 2011).

Condom catheters, also known as urinary sheaths, can be a useful adjunct for management of urinary leakage in men. These disposable devices surround the penis and are connected to a urinary drainage collection bag. Some men use these in selective settings such as when they go out of their home or participate in social activities. They can also be used at night to help control urinary leakage and decrease bother from nocturia, particularly in men with mobility limitations that make traveling to the toilet difficult or dangerous. Proper sizing of condom catheters and good skin hygiene are essential for successful use. Skin breakdown or necrosis can occur if the device is not properly maintained or if the condom is too small or placed too tightly around the penile shaft.

Urethral clamps and plugs are available in a wide variety of styles. Cunningham and other types of penile clamps should be used only during the daytime and need to be moved to different locations on the penile shaft every few hours to prevent tissue injury or necrosis. Men need to have adequate hand dexterity and cognitive function to use these types of devices successfully. Urethral caps and plugs have been developed for use in women. These offer the advantage of a nonsurgical option but can be difficult to use because of the disposable design, which requires removal and replacement with every void and associated costs. They also require adequate hand dexterity for routine use. These types of devices may be most useful when used selectively to prevent urinary leakage during exercise or other physical activities, or when leaving the home environment.

Bladder Outlet Obstruction

BOO, particularly resulting from BPH or urethral stricture disease, is more common in elderly than in younger patients. Incidence and prevalence rates for BPH, UI, and other forms of voiding dysfunction in men increase with advancing age (Griebing, 2008; Parsons et al, 2008; Irwin et al, 2011). Evidence-based guidelines for evaluation and management have been developed (McVary et al, 2011). However there still appears to be quite a bit of variation in initial evaluation and management among different practices (Strope et al, 2011; Erickson et al, 2014).

The spectrum of both medical and surgical therapies should be considered, and decisions based on each patient's unique situation. In many cases, men want to start with medications before considering surgical therapy. Recent research has led to an increased use of combination therapy with α -blockers and other forms of medication including phosphodiesterase type (PDE5) inhibitors, antimuscarinic agents, and 5 α -reductase inhibitors (Chung et al, 2011; Regadas et al, 2013).

Tissue ischemia caused by oxidative stress and diminished blood flow to the pelvic organs and prostate is a factor that theoretically could worsen BOO symptoms. Animal studies have suggested that an antioxidant diet may help to reduce the negative effects of this condition (Bisogni et al, 2012). There is great interest in whether similar results might be possible in humans.

Surgical therapies can be very useful, particularly in men with a history of acute urinary retention caused by BOO or in those who have not experienced sufficient improvement on pharmacotherapies. In addition to traditional transurethral resection, laser surgery and other minimally invasive forms of therapy have been used successfully in elderly men with BPH (Kuntz et al, 2008; Elshal et al, 2013). Bipolar plasmakinetic TURP has been used to reduce bleeding during surgery in elderly men with larger prostate glands (Coskuner et al, 2014).

Care must be taken when considering treatment of elderly men with BPH, particularly those with associated neurologic conditions such as Parkinson disease, Shy-Drager syndrome, multiple sclerosis, or other underlying disorders. These can exacerbate bladder storage and voiding problems and may increase risk for UI and other negative outcomes. Even after relief of BOO, DO may not completely resolve. This can be frustrating to patients and may continue to require therapy to control bothersome symptoms. TURP has traditionally been avoided in men with combined BOO and detrusor underactivity, although newer data have been challenging this long-held concept (Ou et al, 2012).

In select patients who are not good surgical candidates, urethral stents may be considered as an option (Milroy and Allen, 1996). Complications of urethral stents include technical issues and difficulty with tissue overgrowth and urethral strictures. However, in select men who might otherwise be dependent on indwelling catheter drainage, urethral stents may offer a viable treatment alternative (Gesenberg and Sintermann, 1998; Bozkurt et al, 2013). Urethral reconstruction may be feasible in select elderly men, and good outcomes have been reported using dorsal onlay skin grafts among other techniques (Schwettner et al, 2010).

Ophthalmic side effects of medications used to treat BOO need to be considered carefully in elderly men. The floppy iris syndrome is a condition that causes billowing of the iris during surgical cataract extraction and lens implantation (Bell et al, 2009; Friedman, 2009). It is important that elderly men on tamsulosin and other medications for treatment of BOO inform their eye surgeon before any procedure. These medications may need to be discontinued for at least a week before planned cataract surgery.

Underactive Bladder and Urinary Retention

UAB is a condition characterized by poor bladder emptying that is not necessarily caused by BOO. It likely encompasses multiple causes and clinical conditions (Taylor and Kuchel, 2006). This may be related to both a failure of the detrusor muscles to contract and a failure of the neural pathways to properly stimulate the bladder

(Smith, 2010). The ICS defines the term *detrusor underactivity* as "a contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or a failure to achieve complete emptying within a normal time span" (Abrams et al, 2002). The specific term *underactive bladder* has not yet been defined by the ICS.

Research on UAB is relatively new, and there are few epidemiologic studies on the condition. (Griebing, 2013a). In a population-based survey, 23% of 633 respondents indicated they had difficulty emptying the bladder (Valente et al, 2014). In a similar study of older adults who had undergone urodynamic testing for voiding dysfunction, 40.2% of men and 13.3% of women were diagnosed with detrusor underactivity (Jeong et al, 2012). **Both structural and functional changes appear to lead to development of UAB.** Ultrastructural studies have demonstrated that aging is associated with an increased deposition of collagen and a reduction in the ratio of smooth muscle to connective tissue (Elbadawi et al, 1993, 1997).

Progression of prior OAB or BOO may be involved in this process (Chancellor, 2014). Alterations in both active contraction and passive muscle stretch appear to play an important role as well (Young et al, 2013). Bladder ischemia has been linked to subsequent development of detrusor dysfunction and UAB. Studies using color flow Doppler ultrasound have shown that there is a quantifiable decrease in pelvic arterial blood flow in some elderly patients with LUTS. This may be a result of atherosclerosis or other vascular insufficiency (Pinggera et al, 2008; Kim et al, 2010a). The development of animal models of UAB will help advance future research on this topic (Tyagi et al, 2014a).

Several different forms of UAB have been identified in geriatric patients, and this can manifest in several different ways. Detrusor failure can be caused by sacral nerve injury with development of cauda equina syndrome. Patients typically experience lower extremity weakness and problems with gait and mobility. Some may develop frank paraplegia. In these patients the bladder typically has a low pressure during filling and does not contract well to void.

Acute urinary retention can be caused by BOO or detrusor failure. Decompression with an indwelling urinary catheter is usually required initially, with careful monitoring for postobstructive diuresis and electrolyte fluctuations. Evaluation for renal insufficiency or hydronephrosis is also warranted. **Catheter clamping before removal should be avoided, because this has not been shown to be of any clinical benefit and will serve only to induce discomfort.** In men with a history of BOO from BPH, initiation of medical therapy with α -blockers or 5 α -reductase inhibitors can be considered.

DHIC is one of the more common conditions seen in geriatric practice (Resnick and Yalla, 1987; Yalla et al, 2007). This condition is characterized by urinary urgency and frequency resulting from DO during bladder filling and storage. However, during the voiding effort, the bladder contracts poorly and does not empty well. Because of this, patients experience both urinary urgency and frequency but incomplete voiding and urinary retention.

Adequate treatment of UAB can be complex. In many patients it may require intermittent bladder catheterization. However, in some patients this may be difficult or impossible because of comorbidity such as severe hand arthritis or cognitive impairment. Augmented voiding techniques including the Credé maneuver or bladder tapping may be used by some patients (Ersoz et al, 2013). Care should be taken to monitor the upper urinary tract in these patients for development of hydronephrosis or other evidence of clinical deterioration.

Unfortunately, there is currently no effective pharmacologic therapy that improves bladder emptying in UAB. Theoretically, the cholinergic medications should lead to improved smooth muscle contraction in the urinary bladder, but **medications such as bethanechol have failed to demonstrate clinical efficacy.** A recent Cochrane review concluded that this medication should not be used for the treatment of urinary retention or UAB (Lapitan et al, 2013). Increased research and education on UAB will help advance our understanding of the clinical condition in geriatric patients (Griebing et al, 2014).

Nocturia

Nocturia is one of the most common and bothersome urinary conditions that occurs in elderly patients (Weiss and Blaivas, 2000; Wehrberger et al, 2012). The ICS defines *nocturia* as “getting up from sleep in order to void” (Abrams et al, 2002). This is usually preceded and followed by additional episodes of sleep. Polysomnography studies have documented that a majority of episodes of nocturia occur during superficial rapid eye movement (REM) sleep (Krystal et al, 2010; Bal et al, 2012). However, waking to urinate can also lead to difficulty getting back to sleep, with 46% of older adults in one survey reporting this as a substantial clinical problem (Endeshaw, 2009). Affected older adults also report worse disease burden, poor overall sleep quality, and an increased rate of falls compared with those who fall back to sleep more easily. Sleep duration is often decreased in older adults, and this has been identified as an independent risk factor for nocturia in elderly patients (Udo et al, 2009). Several biochemical processes appear to influence both nocturia and nocturnal polyuria. Obstructive sleep apnea results in decreased antidiuretic hormone (ADH) secretion and increased brain natriuretic peptide (BNP), which can lead to nocturnal polyuria (Hoshiyama et al, 2014). Nighttime melatonin secretion is inversely proportional to nocturia in older adults (Obayashi et al, 2014). Worse nocturia severity has also been linked to progression of underlying neurologic disorders such as Parkinson disease (Vaughan et al, 2013). Improved understanding of these complex associations between comorbid conditions and nocturia may help to improve future options for diagnosis and treatment.

The epidemiology of nocturia is complex and is linked to underlying risk factors associated with the condition. There appear to be some underlying differences in nocturia between men and women as a result of a variety of anatomic and physiologic factors (Tikkinen et al, 2006; Bing et al, 2007, 2008). An epidemiologic survey of 6000 people in Finland revealed multiple associated conditions including urinary urgency, snoring, BPH in men, and overweight and obesity (Tikkinen et al, 2009). At an individual level, urinary urgency appears to be one of the strongest correlated conditions. However, none of the conditions studied accounted for more than 50% of cases, even in age-adjusted risk analysis. Some modifiable behavioral factors have also been associated with nocturia, including alcohol consumption and cigarette smoking (Lee et al, 2012).

Nocturia can have a substantial negative impact on QoL. In general, one episode of nocturia per night is well tolerated by most people and is usually considered normal. However, two or more episodes of nocturia nightly have been linked to diminished sleep quality, reduced overall and health-related QoL, depression, and other detrimental clinical outcomes (Tikkinen et al, 2010). Increased rates of morbidity and mortality have both been linked to nocturia (van Doorn et al, 2012). Worse nocturia severity has been directly correlated with increased rates of complications including falls, fractures, and other negative clinical outcomes (Bing et al, 2007, 2008). This association appears to be independent of age and is more associated with severity of nocturia (Temml et al, 2009). This is true both in community-dwelling older adults and in those living in nursing home and other facilities (Galizia et al, 2012). Falls are associated with increased rates of both hip and long bone fractures, which in turn increase the risk for immobility and mortality (Nakagawa et al, 2010). Fat embolization from bone fractures can cause stroke and pulmonary embolus. Falls associated with nocturia can be caused by a number of factors including problems with balance and gait, attempting to travel to the toilet in the dark, navigating obstacles that may be in the path to the bathroom, and other factors.

Even in younger people, increased rates of nocturia have been associated with increased mortality (Fitzgerald et al, 2007; Nakagawa et al, 2010; Kupelian et al, 2011). This is likely a result of the fact that nocturia may be a marker condition of other comorbid diseases including cardiovascular and pulmonary diseases.

A careful history is useful in helping to identify potential causes of nocturia. Multiple different conditions can contribute to noctu-

ria. These include nocturnal polyuria, medications that increase urine production or disrupt sleep, diabetes insipidus, SIADH, hypertension, CHF, pulmonary or peripheral edema, obstructive sleep apnea, and other sleep-related disorders (Guilleminault et al, 2004; Burgio et al, 2010). A fluid intake and output diary can be helpful in differentiating causes of nocturia in many older patients.

Successful treatment of nocturia in elderly patients can be challenging and complex. Because the cause of nocturia is typically multifactorial, single therapies provided in isolation are often ineffective, and multimodal therapy targeting different causes may be required. Behavioral therapies and medications have been shown to be more effective in combination and should be focused on the underlying mechanisms of nocturia (Vaughan et al, 2009). Behavioral strategies that have shown promise include limitation of evening fluid consumption, PFME training, delayed voiding methods, and urge suppression techniques (Johnson et al, 2013). Use of diuretics during the earlier portions of the day may help to off-load excess fluid. Patients with peripheral edema may benefit from lying in a recumbent position earlier in the day to create a postural diuresis and off-load some of this excess fluid before retiring to bed for the night. Use of pressure gradient stockings may also be helpful.

Obstructive sleep apnea is often treated with continuous positive airway pressure (CPAP) ventilation support. In patients with incomplete bladder emptying and nocturia, CIC performed at bedtime may permit better sleep by improving functional bladder capacity at night, thus allowing the bladder more time to fill during sleep. Use of assistive devices such as bedside commodes or handheld urinals can help to reduce difficulties associated with nocturia in older adults. This can be particularly useful in those with mobility limitations or a strong risk for falls during nighttime toileting.

Desmopressin has been advocated as a potential pharmacologic treatment for nocturia caused by nocturnal polyuria. However, substantial caution should be exercised when using this medication, particularly in geriatric patients. Older adults tend to have less capacity for compensatory regulation of electrolyte imbalance. Hyponatremia is one of the major risks associated with use of desmopressin in elderly patients (Weatherall, 2004; Rembratt et al, 2006). Development of clinically significant hyponatremia can occur even several months after starting medication (Bae et al, 2007). In addition to potential hyponatremia, there are multiple other potential contraindications for use of vasopressin in older adults. These include risk of exacerbation of underlying heart failure, renal insufficiency, alterations in potassium and calcium excretion, and other electrolyte disturbances.

The primary risk is hyponatremia, which can be profound in some cases and can lead to negative outcomes including agitation, confusion, or coma. Staggered administration of desmopressin and furosemide has been shown in short-term research to improve outcomes and possibly reduce associated risks of electrolyte abnormalities (Fu et al, 2011). Newer formulations with rapidly dissolving oral preparations or “melts” that do not require water consumption for administration may be associated with lower rates of complications. Low-dose therapy (<0.2 mg) appears to be effective in most cases (Song et al, 2014). Dosage requirements may differ in men and women because of underlying physiologic differences, with older women appearing to require lower baseline doses (Yamaguchi et al, 2013). Clinical trials of desmopressin for treatment of nocturia in elderly patients are still ongoing, and this medication is not currently approved in the United States for this purpose.

Fecal Incontinence

Older adults commonly experience difficulty with bowel function. This can be caused by changes in motility, absorption, and other physiologic alterations associated with the aging process. Fecal impaction can actually manifest as diarrhea as a result of liquid material oozing around a stool bolus leading to FI, particularly in those with low anal closure pressures. Elderly patients often

experience dual bowel and bladder incontinence because the same neural pathway controls both of these processes. **FI can be particularly problematic in older adults** (Quander et al, 2005; Hayden and Weiss, 2011). Health care providers must specifically ask about bowel function during clinical assessment. Older patients may not voluntarily provide information on bowel problems because of embarrassment or other personal reasons.

Reported prevalence rates of FI range from 17% of community-dwelling women older than age 85 to 43% of elderly women residing in nursing home facilities (Townsend et al, 2013). More recent data confirm these prevalence rates, with 17.3% of community-dwelling older adults reporting having experienced accidental bowel leakage (Gorina et al, 2014). Among those receiving home health care services, FI was reported by 13.1% of those aged 65 to 74 years and 20.8% of those aged 85 years and older. Patients in hospice care have reported prevalence of UI of 9.9%, FI of 24.0%, and dual incontinence of 28.0% (Gorina et al, 2014). **UI is highly correlated with FI, and older adults with one condition are at increased risk for developing the other problem.** Rectal hypersensitivity and anatomic defects of the anal sphincter muscle complex have been identified as additional risk factors for development of FI (Lewicky-Gaupp et al, 2009).

Both constipation and FI are highly prevalent among nursing home residents. In one study, 81.1% of elderly nursing home residents had an average of three bowel movements every 5 days, and only 29% were classified as continent (Schnelle et al, 2009). These rates improved substantially to 74% continent after use of relatively simple targeted therapies including prompted toileting. Multimodal therapy may also be quite useful in older adults with UI and FI and has been shown to substantially reduce problems with constipation (Schnelle et al, 2010).

Continence Promotion and Advocacy

Education of patients and providers is a critical aspect of continence promotion for older adults (Newman et al, 2013). There are a number of common myths about UI in geriatrics that hamper appropriate evaluation and treatment in many cases. **UI should never be considered a normal or inevitable part of the aging process.** Patients and providers need to be aware that there are often treatments that can substantially improve and in some cases completely eliminate incontinence. Many of these successful therapies involve nonsurgical methods. Surgery may be an appropriate and successful treatment option for some select patients with specific clinical indications.

Enhanced public awareness may improve access to and use of care services. An analysis of data from more than 82,000 elderly Medicare beneficiaries demonstrated a 37% prevalence of UI, but only 41% of those who experienced UI had spoken with a health care professional about their symptoms (Chang et al, 2008). Some have argued that systematic screening for UI may be beneficial among older women (Visser et al, 2013). In a survey study, elderly women indicated that they did not seek help because they did not feel their symptoms were severe enough to justify treatment (73.4%), they had already found a way to cope with symptoms (57.3%), they thought UI was a normal part of aging (46.9%), they thought there was no cure or effective treatment available (23.8%), or their general practitioner did not ask about UI (20.3%) (Visser et al, 2012). These findings demonstrate that there is a role for improved public and professional education and a need for advocacy on this topic.

Targeted continence promotion programs for older adults have been successful in the community setting. These can increase knowledge among patients with incontinence and have been shown to encourage help-seeking and self-treatment behaviors (Tannenbaum et al, 2010). Evidence-based self-management tools have been developed and can be useful in this process for motivated patients (Holroyd-Leduc et al, 2011). Future research will help improve understanding of the best methods for dissemination of this type of information among older adults with UI and other urologic conditions.

Pelvic Organ Prolapse

POP is a common clinical condition seen in elderly women. Incidence and prevalence of POP both increase with advancing age, but like other conditions it should not be considered an expected or normal part of the aging process. **Risk factors for POP in elderly women include history of prior pregnancy and vaginal delivery, prior pelvic trauma, and changes in tissue quality and structure.** Biopsy studies have shown that with advancing age there is a progressive loss of smooth and striated muscle and an increase in collagen and other connective tissues in the urogenital diaphragm (Betschart et al, 2008). Apoptotic changes in pelvic floor tissues also occur that can predispose to prolapse (Saatli et al, 2014). These changes lead to laxity of pelvic floor architecture and subsequent loss of support.

Evaluation of POP in elderly women requires careful history and physical examination. Many older women describe the sensation of a vaginal bulge. This is often worse after physical activity or in the late afternoon or evening after the patient has been up and about during the day. **Severe prolapse can be associated with difficulties with urination or defecation as a result of urethral angulation or anatomic changes in rectal configuration.** Some women, particularly with a large prolapse, will describe a need to manually reduce the bulge with their fingers to void or defecate. The clinician should attempt to reduce the prolapse during pelvic examination. The position of the uterus, if present, and the vaginal cuff should be assessed. Prolapse of the vaginal apex may require specific surgical fixation to either the sacrospinous or uterosacral ligaments.

Pessaries can be quite useful in treatment of POP in elderly women. These come in a wide variety of shapes and sizes and need to be individually fitted to the patient. When correctly sized, the patient is usually unable to feel the pessary in the vagina. If the pessary is too small, it will tend to fall out with physical activity or straining. If it is too large, the pessary will tend to be uncomfortable and may cause tissue irritation or erosion over time. Pessaries should be removed and cleaned periodically, and the tissue integrity checked (Khaja and Freeman, 2014). In patients with limited hand dexterity or cognitive impairment, this might require assistance from a care provider. Visiting nurse services can sometime help with pessary management. It is important that the pessary be routinely checked to avoid complications associated with neglect including erosion into surrounding structures or vaginal infections. Concomitant use of vaginal estrogen can be useful to help prevent some of these complications.

Pessaries offer potential advantages of avoiding surgery and allowing patients self-control over the clinical situation. Many older women do very well with pessaries and continue to use them over time. Factors associated with increased long-term success include age 72 years or older, careful fitting, and provision of clear instructions for use (Friedman et al, 2010). Successful pessary use has been associated with improved overall and health-related QoL, and improved body image in elderly women with POP (Patel et al, 2010). However, some older women do not like using pessaries or do not want to be bothered with having to remove and replace the device on a regular basis. If the pessary improves genitourinary symptoms but the patient does not like using the device, this may indicate that she could experience a good functional outcome with surgery.

Surgical repairs for POP are feasible even in elderly women. These procedures can be done using vaginal, laparoscopic, robotic, or open surgical techniques. A variety of both native tissue repairs and procedures using biologic or mesh grafts can be used. Several studies have shown that mesh repairs can be successful for treatment of POP even in elderly women (Shah et al, 2004; Gabriel et al, 2010). However, as with any surgical treatment, patients do need to be very carefully counseled about use of mesh grafts and potential risks and benefits associated with this technique (Mohammed et al, 2013; Reynolds et al, 2013). Surgical repair with native tissue grafts such as autologous or cadaveric fascia has also been successfully used in elderly women with POP and UI (Carey and Leach, 2004). Many older women may choose to avoid or delay surgery for POP.

However, in those who do eventually undergo surgical repair, there is evidence to suggest that increased time between development of symptoms, particularly after menopause, and subsequent surgery is associated with poorer subjective postoperative improvements (Ahn et al, 2010).

One surgical option that can be considered for select older women with POP is colpopcleisis with perineoplasty. This procedure essentially reduces the prolapse and closes the vaginal introitus. This should be considered a permanent and nonreversible procedure. Two different surgical techniques are used. In women who still have their uterus, the procedure is usually performed leaving lateral channels on each side of the vaginal vault to permit uterine drainage. Total colpopcleisis is used in women after hysterectomy and consists of a denudation of the vaginal mucosa and subsequent reduction and conical closure of the prolapse. Perineoplasty is performed to reduce the size of the vaginal introitus and prevent recurrence of bulging from the outlet. Women need to be expressly counseled that penetrative sexual activity will not be possible after this type of surgery. However, it does not preclude other forms of erotic or sexual activity. Reported success rates with colpopcleisis have been quite high, and rates of subsequent regret after having the procedure are quite low (Koski et al, 2012; Vij et al, 2014). Colpopcleisis has been shown to improve both bladder and bowel symptoms in women with a history of significant prolapse (Gutman et al, 2010; Vij et al, 2014).

Urethral caruncle is a protrusion of tissue from the urethra and is seen more commonly in elderly than in younger women. In most cases these are painless and benign. Unless they are quite large, they often do not affect voiding function. (Ozkurkcugil et al, 2010). Topical estrogen therapy is useful and often leads to tissue contraction and involution of the caruncle. Surgical excision is not typically necessary. However, if surgery is performed, care must be taken to avoid damage to the external urethral sphincter, which could lead to stress UI.

Urinary Tract Infections and Asymptomatic Bacteriuria

UTI is one of the most common clinical conditions seen in older adults, and particularly in elderly women. **It is important to distinguish between symptomatic UTIs and asymptomatic bacteriuria.** Symptomatic infections require evaluation and treatment, usually with antibiotic therapy. **Urinary cultures are strongly recommended to verify the infection, determine the associated bacterial organism, and identify antibiotic susceptibility or resistance patterns.** Empiric treatment with antibiotics may need to be modified depending on the results of the urine culture and drug susceptibility panels. If older adults have difficulty providing a clean-catch urine specimen, a catheterized urine sample should be obtained to help with accurate diagnosis (Gordon et al, 2013).

Symptoms of acute UTI may include urinary urgency and frequency, cloudy or foul-smelling urine, fever, bladder pain, and dysuria. However, many older adults may not show these symptoms as a result of alterations in the immunologic or other systems (Arinzon et al, 2012). Instead, **elderly patients may experience what have been called "atypical" symptoms in other populations.** These include confusion, agitation, lethargy, and anorexia, among others (Juthani-Mehta et al, 2009). Acute UTIs in older adults can lead to clinically symptomatic delirium (Eriksson et al, 2011). Urine cultures should be checked to determine if an associated UTI is present, and appropriate antibiotic therapy initiated if indicated.

More complex UTIs such as pyelonephritis are often associated with underlying comorbidity including diabetes, anemia, and urolithiasis (Kang et al, 2008). Antibiotic therapy should be instituted in most cases and should be based on culture and drug susceptibility results. **Urosepsis in elderly patients can be quite serious, and increased mortality is seen in this population.** Associated factors that increase the risk of mortality from bacteremia in geriatric patients include advanced age (≥ 85 years), chronic renal disease, severe cognitive impairment, and hypothermia (Rebelo et al, 2011). Hospital-acquired UTIs also appear to carry a greater risk for mortal-

ity than community-acquired infections, at least among older adults in acute hospital settings (Chin et al, 2011). Treatment of these serious infections typically requires directed antibiotic therapy and fluid resuscitation. Fungal UTIs occur more commonly with advanced age, and particularly in patients with reduced immune status, including those with a history of transplant, advanced human immunodeficiency virus (HIV) disease or acquired immunodeficiency syndrome (AIDS), or poorly controlled diabetes. Treatment with antifungal agents such as fluconazole can be effective in many cases (Fraissee et al, 2011).

In contrast, asymptomatic bacteriuria is very common in older adults and in general does not require therapy. Approximately 10% to 20% of all older women living in the community will have bacteria in their urine on routine analysis, and rates are typically higher in long-term care and other institutional settings (Varli et al, 2012). Although less common than in women, rates of asymptomatic bacteriuria still approach about 10% in community-dwelling elderly men (Juthani-Mehta, 2007). Asymptomatic bacteriuria has been associated with increased serum and urinary inflammatory cytokines, but this does not necessitate antibiotic therapy (Chang et al, 2012b). Dipstick urinalysis can be useful in diagnosis, particularly in long-term care settings, with a goal of correctly differentiating symptomatic UTI and asymptomatic bacteriuria and reducing overuse of antibiotics when not clinically indicated (Bonnal et al, 2008; Sundvall and Gunnarsson, 2009). The AGS has included avoidance of antimicrobial therapy for asymptomatic bacteriuria as one of their original five things to avoid or question as part of the Choosing Wisely campaign (AGS Choosing Wisely Workgroup, 2013).

A variety of clinical factors increase risk of UTIs in older adults. Catheter-associated UTIs are one of the most prevalent types of infection seen in acute care hospitals and other inpatient settings (Daniels et al, 2014). CIC can reduce infection rates in patients with chronic urinary retention, although one study of elderly stroke survivors did show a trend toward increased infection rates (Stott et al, 2009). However, this association disappeared after controlling for stroke severity. BMI has been linked to UTI in older adults, with both obese and significantly underweight elderly patients having higher rates of infection (Dorner et al, 2010).

Administration of vaginal estrogens can be quite useful in reducing rates of symptomatic UTIs in elderly women. After menopause, there is loss of the natural acidification of vaginal fluid. This increased alkalinity prevents growth of *Lactobacillus* species, the natural flora in the vaginal vault. *Lactobacillus* is an important part of the natural host-defense mechanism to prevent UTI. **Addition of topical vaginal estrogens can help reacidify vaginal fluid, which permits growth of *Lactobacillus* species.** This in turn helps to kill off pathogenic bacteria that cause symptomatic UTI. The medication comes in several different forms including vaginal creams, vaginal tablets or suppositories, and a small ring-shaped device that releases estrogen continuously over several months. If using creams, a small amount with fingertip application in the vagina is usually sufficient if administered three times weekly at bedtime. Vaginal estrogens are in general contraindicated in women with a personal history of either breast or uterine cancer. However, emerging data suggest that women with known estrogen receptor negative (ER-) breast cancers may be able to safely use this type of therapy. The amount of estrogen absorbed systemically is usually low. Patients with this type of history should consult with their oncologist before starting therapy.

The use of cranberry juice or other cranberry supplements is popular with many people as a form of UTI prophylaxis. This works by interaction between fructose and proanthocyanidins in cranberry and bacterial cell walls, which leads to inhibition of adherence to the urothelium. Although many people describe clinical efficacy, results in scientific studies have been mixed. Recent data from a randomized, double-blind, placebo-controlled trial in nursing home residents showed there were reductions in infection rates, but these were limited to those patients with a previously high rate of infections (Caljouw et al, 2014). The overall cost-effectiveness of cranberry therapy also appears to be limited based on observed

clinical outcomes and economic analysis, which demonstrated an estimated cost exceeding \$5200 annually to prevent one clinically significant UTI (van den Hout et al, 2014).

Chronic antibiotic use for UTI prophylaxis should be avoided, unless no other options are available, because of an increased risk of development of resistant organisms. The choice of antibiotics is also important. Although it can be useful for short treatment of acute infections, nitrofurantoin should be avoided for chronic prophylaxis because of risks of pulmonary fibrosis and associated complications in older adults. In addition, it should be avoided in those with impaired renal function, defined as creatinine clearance (CrCl) below 60 mL/min (Leung et al, 2007; AGS Beers Criteria Update Expert Panel, 2012).

Evaluation and management of UTIs in nursing home and assisted care settings require special consideration. Overuse of antibiotics is very common in these locations, which may be a result of the substantial challenge of correctly diagnosing symptomatic UTIs in older nursing home residents who may have subtle or atypical symptoms (Juthani-Mehta et al, 2007; D'Agata et al, 2013; Kistler et al, 2013). In addition to avoiding treatment of asymptomatic bacteriuria, careful antibiotic selection is important. **Use of antibiotics based on local prevalence of specific organisms can help guide therapy.** Guidelines from professional organizations can also help to reduce overuse of specific antibiotics that may increase the risk of developing drug-resistant infection in given locations (Daneman et al, 2011; Fagan et al, 2012). As with acute care hospitals, there are data to suggest that environmental contamination in nursing homes may increase the risk of some types of infections including methicillin-resistant *Staphylococcus aureus* (Murphy et al, 2012). Strict hand washing and other infection-prevention methods can help to substantially reduce this risk.

The costs associated with evaluation and treatment of UTIs in the United States are staggering and surpass those for almost all of the other major genitourinary disorders (Griebing, 2005a, 2005b). This is a result of multiple factors including a high incidence and prevalence of UTIs, but also excess evaluation and overtreatment of conditions that may not require therapy including asymptomatic bacteriuria. A sizeable volume of clinical care for UTIs is provided in emergency room settings, which exponentially increases associated costs.

Hematuria

Hematuria is a common clinical condition seen in elderly patients, particularly those on anticoagulants. Patients with gross or persistent microhematuria should undergo clinical evaluation (Davis et al, 2012). The use of anticoagulation is common in older adults, particularly for prevention of stroke in those with atrial fibrillation and other arrhythmias, deep vein thrombosis, and other hematologic disorders. Supratherapeutic anticoagulation, particularly with warfarin, has been associated with an increased risk of developing acute kidney injury (AKI). (Lim and Campbell, 2013).

Genitourinary Trauma

Evaluation and management of genitourinary trauma in elderly patients requires some special considerations. Compared with younger adults, elderly patients are more likely to experience blunt rather than penetrating traumatic injuries. Underlying comorbidity and clinical conditions associated with the aging process put geriatric patients at higher risk for poor outcomes. For example, falls are one of the leading causes of traumatic injuries among older adults, with more than 2.3 million emergency room visits for this annually in the United States (CDC, 2010). The rate of genitourinary injuries caused by falls in geriatric patients is 26.5% compared with 8.4% in younger adults ($P < .0001$) (Bjurlin et al, 2011).

The basic principles of management of genitourinary trauma do not differ considerably based solely on age. The decision for conservative versus more aggressive therapy should be based primarily on the nature of the injury. However, careful consideration of associated comorbidity with medical optimization of these other conditions is essential for successful management. For example, **older adults with osteoporosis may be at higher risk for pelvic fracture resulting from falls compared with those without this associated comorbidity.** Treatment in these patients may require different techniques including greater use of embolization therapy than in younger or healthier patients (Kimbrell et al, 2004). **Men on ADT are at higher risk for hip and long bone fractures because of changes in bone mineral density associated with hormonal therapy** (James et al, 2014). Treatment with agents such as alendronate or zoledronic acid may decrease this fracture risk in these patients (Planas et al, 2009; Campbell et al, 2010).

Older adults are also more likely to require discharge to either a rehabilitation facility or nursing home (13.6% and 18.5%, respectively) compared with younger adults (8.6% and 3.1%, respectively) after acute management for genitourinary trauma (both, $P < .0001$) (Bjurlin et al, 2011). Geriatric trauma is a relatively new scientific field, and additional work will be needed to better identify specific protocols for this population. Early research has shown that inclusion of data on chronic comorbidities in geriatric trauma patients may be superior to traditional measures of vital signs and injury pattern alone in decision making and clinical outcomes (Brooks et al, 2014). In addition, there is interest in creating and validating an index of frailty specific for elderly trauma patients to see if this may influence evaluation, treatment, and outcomes (Joseph et al, 2014).

Prostate Cancer

The evaluation and treatment of prostate cancer in elderly men differs somewhat from the general population. The U.S. Preventive Services Task Force recommendation does not support routine screening for prostate cancer in any group, although this is highly controversial (U.S. Preventive Services Task Force, 2008; Moyer et al, 2012). When prostate cancer screening is performed, it is generally recommended that this be discontinued in men once they reach 70 to 75 years of age. This is because definitive therapy for prostate cancer is typically reserved for men with an estimated remaining life expectancy of 10 or more years (Hoffman et al, 2010). Because the mean life expectancy for men in the United States is approximately 82 to 84 years, most clinicians would argue to limit use of definitive therapy with radical prostatectomy or radiation therapy to those aged 75 years or younger. It is interesting to note that in survey research, about a third of older adults indicate that they would rather not know either their predicted life expectancy or survival probability (Clarke et al, 2008). This can be problematic in relation to discussions about clinical decisions in this population.

Recent research has examined factors that can be associated with recommendations to stop screening, including PSA velocity and genetics, and risk factor group profiles (Tang et al, 2010, 2011). Despite these recommendations, many older men choose to continue screening for various personal reasons (Caire et al, 2010; von Wagner et al, 2013). There is also some variation among practitioners in terms of following these guidelines for discontinuing screening in geriatric men (Hudson et al, 2009; Bynum et al, 2010; Whittle, 2010). In contrast to routine screening, targeted diagnosis in select patients at risk for prostate cancer can help to guide therapy, even if it is not done with curative intent (Paterson et al, 2013). This can help in the overall care and management of disease in older men.

There are a number of caveats that must be considered based on the overall clinical situation for each man. The AUA has published guidelines on treatment of clinically localized prostate cancer that include considerations related to overall health, comorbidity, and age (Thompson et al, 2007). The International Society of Geriatric Oncology recently published results of a study indicating the importance of including assessment of ADL and IADL function in the care decisions for elderly men with prostate cancer (Droz et al, 2010). The combination of functional status and disease burden combined with predicted longevity and other parameters may help with this complex decision process.

Although prostate cancer in elderly men is often an indolent, slow-growing disease, some patients have more aggressive cancers (Scosyrev et al, 2012; Kunz et al, 2013). Various factors may predispose to more advanced prostate cancer in elderly men, including a history of hypertriglyceridemia (Hayashi et al, 2012). However, other studies continue to show that most elderly men die of other diseases including cardiovascular and pulmonary disorders (Jeong et al, 2009; Ketchandji et al, 2009).

Several studies have shown that elderly men who undergo radical prostatectomy can have good clinical outcomes that in many cases are equivalent to those seen in younger men (Greco et al, 2009; Namiki et al, 2010; Pierorazio et al, 2010). However, other studies have demonstrated that elderly men are at higher risk for negative clinical outcomes including upgrading and upstaging of their disease, greater risk for biochemical recurrence, and surgical complications (Richstone et al, 2008; Trinh et al, 2012; Ko et al, 2013). Radiation therapy is often used in elderly prostate cancer patients because it is considered to be less invasive. It has been associated with acceptable clinical outcomes including health-related QoL, although as with any treatment there are risks for incontinence and erectile dysfunction, among others (Namiki et al, 2010; Mirza et al, 2011). UI can be particularly bothersome in elderly men treated for prostate cancer. This can have substantial negative effects on activity, mood, and QoL (Park et al, 2012; Kopp et al, 2013). Cryotherapy has been advocated as a possible treatment for elderly men with

organ-confined prostate cancer who may not be candidates for more invasive forms of therapy (Dhar et al, 2011).

In elderly men with metastatic prostate cancer, hormonal therapy or chemotherapy may be used to reduce disease progression. Docetaxel has been shown to improve overall survival in early trials (Miyake et al, 2012). ADT can certainly be useful in select patients but is also associated with potential adverse effects, particularly in elderly men. ADT has been shown to increase the risk of cardiovascular disease, myocardial infarction, and diabetes in elderly men (Keating et al, 2013). Changes in bone mineral density are associated with increased risk of fractures as a result of osteoporosis and osteopenia (Shao et al, 2013). These effects can be tempered by the use of agents such as alendronate and zoledronic acid (Planas et al, 2009; Campbell et al, 2010). Other negative side effects include decreased libido, gynecomastia, hot flashes, and sexual dysfunction. ADT has also been linked to development of sarcopenia in elderly men (Reis et al, 2009). Finally, the cost of ADT may be a barrier to ongoing therapy for some patients (Krahn et al, 2011).

Bladder Cancer

Bladder cancer is one of the most common urologic malignancies seen in the geriatric population, and incidence and prevalence both increase substantially with advancing age. Owing to the long latency of carcinogen exposure, age is one of the most important independent risk factors for development of bladder cancer, with a median age at diagnosis above 70 years (Shariat et al, 2010b). In general, diagnosis is similar in elderly and younger patients. Diagnosis of bladder cancer is associated with negative effects on overall and health-related QoL, with reductions in both physical and mental health domains (Fung et al, 2014).

Guidelines have been developed for evaluation and management of bladder cancer, and an audit study showed that these are generally followed (88.8%) in elderly patients (Bolenz et al, 2010). The role of tumor restaging with repeat resection has been demonstrated in elderly patients, although rates have been shown to be quite low among Medicare beneficiaries (Skolarus et al, 2011). This can be very useful to help identify muscle-invasive disease, which may require different treatment. It is interesting to note that bacille Calmette-Guérin (BCG) therapy has shown decreased efficacy in elderly patients with non-muscle-invasive bladder cancer compared with younger patients (Margel et al, 2011). This may result from an age-related decrease in the immune system and reduced ability to mount an immune response to therapy in geriatric patients.

Treatment for muscle-invasive bladder cancer has usually focused on surgical extirpation with radical cystectomy and urinary diversion. From a surgical standpoint, this is one of the most invasive and potentially morbid surgeries done in the field of urology. In addition, many of these patients have substantial underlying comorbidity. For example, the condition is strongly linked to a history of smoking, which can predispose to lung disorders such as COPD and restrictive airway disease. These increase the risk of anesthetic complications in this already vulnerable population.

Multiple studies have demonstrated that with careful preoperative planning and intraoperative and postoperative management, radical cystectomy can be accomplished safely even in elderly patients (May et al, 2007; Guillotreau et al, 2012). This appears to convey a potential survival advantage in many patients (Tyritzis et al, 2012). However, this needs to be evaluated within the context of overall health and comorbidity. Many patients with bladder cancer may die of other competing conditions, and this must be considered when making treatment decisions for elderly patients with muscle-invasive bladder cancer (Fisher et al, 2009; Resorlu et al, 2009; Donat et al, 2010). Some studies have shown an increased rate of perioperative and postoperative complications in elderly patients undergoing radical cystectomy, likely as a result of other chronic disease and functional status (Lund et al, 2010; Liberman et al, 2011). Sarcopenia, a key component of the frailty phenotype, appears to be a predictor of postoperative complications

in elderly women undergoing radical cystectomy (Smith et al, 2014a). Diminished performance status has been shown to be a negative predictor of outcomes among geriatric patients treated for muscle-invasive bladder cancer (Weizer et al, 2007).

Bladder-sparing therapies with endoscopic resection and adjuvant chemotherapy or radiation have been used in research in geriatric patients with muscle-invasive bladder cancer. Some studies have shown similar survival rates for more conservative therapy compared with radical cystectomy (Martini et al, 2013). However, overall time in the hospital is often longer for those treated with bladder-sparing therapies, and this can have a negative effect on remaining QoL (Wehrberger et al, 2010). Other data suggest that very elderly patients and those with greater clinical comorbidity have poorer outcomes in terms of both overall and cancer-specific survival (Tran et al, 2009; Kohjimoto et al, 2010). Radiation therapy has been used mostly for palliation of significant bleeding in patients who are otherwise not suitable surgical candidates (Kouloulis et al, 2013). This therapy appears to be well tolerated in these select patients.

Kidney Cancer

Kidney cancer is often diagnosed as an incidental finding in geriatric patients undergoing abdominal imaging for other conditions. Over the past 30 years, there has been a steady increase of 2% to 3% annually in the incidence of kidney cancer diagnoses (Chow et al, 1999). Although increased rates of kidney cancer have been seen in all age groups, the largest have been identified in those in the seventh and eighth decades of life (Katz et al, 1994). In elderly patients with small tumors, surveillance is feasible and may preclude the need for invasive surgery (O'Malley et al, 2010). Advanced age above 75 years has been identified as a risk for more advanced disease, and older adults may need to be watched with greater caution. It is important to consider overall health and comorbidity when making treatment decisions. Use of measures such as the CCI can be useful in this regard and can help identify those who may be at substantially higher risk with treatment (Charlson et al, 1987; O'Connor et al, 2009).

Older adults have been shown to tolerate both radical and partial nephrectomy. In general, complication rates do not appear to be substantially influenced by chronologic age, but more by comorbidity (Roos et al, 2008; Sun et al, 2012). Laparoscopic and robotic procedures for partial nephrectomy appear to be well tolerated by older adults with similar clinical outcomes and complication rates compared with younger patients (Guzzo et al, 2009; Thomas et al, 2009; Hillyer et al, 2012). However, rates of use of partial nephrectomy in elderly patients still lag behind younger cohorts (Kates et al, 2011). The reasons for this are unclear but may be based on concern over underlying clinical conditions and ability to perform surgery in frailer older adults.

In patients with more advanced disease, cytoreductive nephrectomy has been used successfully in elderly individuals, although some complications including need for transfusion are higher in geriatric patients (Kader et al, 2007; Sun et al, 2012). Subsequent immunotherapy may be difficult in some patients, particularly if they have functional impairments and decreased overall performance status. Radical nephroureterectomy has been described in geriatric patients with upper tract urothelial cancers, although reported cancer-specific survival has been lower in those older than 80 years compared with younger patients (Shariat et al, 2010a).

Testis Cancer

Although testis cancer can occur at any age, most germ cell tumors occur in young men aged 15 to 35. **In geriatric men, the most common testicular malignancy is lymphoma (Shih et al, 2014).** This should be evaluated and treated as a systemic condition because isolated testicular involvement is rare. When germ cell tumors of the testis do occur in elderly men, evaluation and general treatment principles should follow those of younger men. One important caveat is that doses of chemotherapeutic agents may need to be adjusted based on comorbidity that affects renal, hepatic, or pulmonary function. This highlights the need for a thorough geriatric assessment in these patients. With successful treatment, life expectancy approaches that of other elderly men without testis cancer (Wheater et al, 2011).

elderly women. Use of water-based lubricants and vaginal estrogen replacement therapy may be useful in these cases. Many chronic diseases that affect sexual health tend to be under-reported and underdiagnosed among older adults. For example, hypogonadism, erectile dysfunction, and osteoporosis are conditions that influence sexuality and overall health but that frequently remain undiagnosed in elderly men (Frost et al, 2012).

Sexual health has also been closely linked to mental health in older adults, with higher rates of depression noted in those with erectile or sexual dysfunction (Cheng et al, 2007; Korfage et al, 2009). Body image is an important factor with regard to sexual satisfaction and mental health regarding sexuality (Carr et al, 2013). This can be affected by a number of factors including weight, BMI, and history of prior genitourinary cancer surgery or stoma formation. In longitudinal studies of men, regular sexual activity has been identified as a protective factor in continued sexual health and is associated with lower rates of subsequent erectile dysfunction (Koskimäki et al, 2008).

There are important differences in human sexuality between men and women. In comparison to the plethora of data on evaluation and treatment of erectile dysfunction in men, there has been much less research conducted examining sexual response and health needs in elderly women. **Population-based research does show that many elderly women remain interested in sex and have sexual health care concerns that deserve clinical attention** (Huang et al, 2009; Schick et al, 2010). As with men, comorbid disease such as metabolic syndrome and diabetes can have a negative influence on sexual health (Kim et al, 2011b). Older women have been found to place strong emphasis on relationships and psychosocial aspects of sexuality including intimacy (Kim and Jeon, 2013). Improved sexual function has been linked to better self-rated health and life satisfaction in cohort studies of geriatric women (Woloski-Wruble et al, 2010; Thompson et al, 2011). In women who have undergone prior treatment for urologic or gynecologic disease, treatment of the underlying pathology can have a substantial impact on sexual health, and this must be considered in evaluation and treatment (Ratner et al, 2011).

Environmental factors can influence sexual health for many older adults. In some cases, elderly persons may live with extended family or be in situations where privacy for sexual activity may be an issue. **Sexual health in nursing home residents deserves special consideration.** There has been an increased awareness and understanding of this in recent years, and many nursing homes work to accommodate this for residents (Mroczek et al, 2013). This may include allowing couples to live in the same room and share a bed, providing privacy and time free from interruptions or medical care, and offering specific medical and nursing care for sexual health needs. Recent research has worked to develop and validate an assessment instrument specific for sexual health in nursing home residents (Bauer et al, 2014). **In patients with dementia and other cognitive impairment, inappropriate displays of sexual behavior may occur and can be problematic. Specific evaluation and treatment tailored to these issues can be useful in these cases** (Bardell et al, 2011).

Treatment of sexual health problems should be designed to address the needs of each individual patient. This must be done in the context of overall health and comorbidity. For example, elderly men with heart disease may not be candidates for PDE5 inhibitors if they have a history of chest pain and use nitrates or take medications that contradict use of this treatment. Some elderly men may have physical or cognitive impairments that limit the use of other therapies such as penile injections or vacuum erection devices. Surgery with placement of a penile prosthesis may be an option for some patients but could be limited in those who are poor surgical candidates. Some men do well with this, and advanced age alone should not be the deciding factor for selection for surgery (Al-Najar et al, 2009).

Some adults may engage in relatively high-risk sexual behaviors, and this can put them at risk for transmission of sexually transmitted diseases including HIV. Condom use in this age group has been reported to be relatively low overall and may increase risk for some

people (Schick et al, 2010; Choe et al, 2011). This generation was never really targeted in public health campaigns about safer sex, and specific counseling about this is warranted. Some health care providers may lack awareness or expertise about geriatric sexuality. **Clinicians need to appreciate their own level of comfort and knowledge in providing sexual health care in the geriatric population and should seek additional information or consultation with others if needed.**

Sexual orientation is an important factor to consider in sexual health care. To date there has been relatively little research on the specific sexual health needs or goals of elderly lesbian, gay, or bisexual persons. Additional work in this field will help to increase understanding to improve quality of care. Transgendered older adults may also have unique urologic needs including hormonal replacement and care after reconstructive surgery (Gooren and Lips, 2014). Cultural and religious views play an important role in human sexuality and should be considered and respected in the evaluation and treatment of sexual health in the older adult population. **The goal should be to provide sexual health care that is respectful of each patient's needs, desires, and goals of therapy.**

Discharge Planning and Care Coordination

Successful management of geriatric urology patients, particularly those undergoing surgical therapy, requires careful coordination and planning. Within this context, discharge planning is vitally important. **Many older adults admitted to the hospital or who undergo surgery will lose independence of at least one of the ADLs at least temporarily.** This may necessitate assistance from caregivers or transition to another place for care. A variety of options are available after discharge from the acute care hospital, including home health nursing or other care services, inpatient or outpatient rehabilitation, and placement in a skilled care facility. Nearly \$40 billion dollars are spent annually on this type of postdischarge care, which represents about 10% of the total Medicare budget (Robinson et al, 2011). Full recovery to prehospitalization baseline levels can occur but is less common than some level of continued impairment (Gill et al, 2009).

High-quality communication between acute care discharging hospital staff and receiving staff at long-term care facilities can greatly facilitate these transitions (King et al, 2013). Goals of care must be carefully considered, and needs and abilities of family or other loved ones to assist in the process must be assessed. Cost is an important factor, and options may be determined in part by coverage available to individual patients. **Ideally, discharge planning should begin as early as possible when treatment determinations are being made.** If the patient is to return to his or her home in the community, what is the environment like and how will this influence function? Are there stairs in the home, and is the patient able to maneuver them safely? What are the toilet facilities like in the home, and are modifications such as grab bars, a bedside commode, or other accommodations needed? Input from professionals in multiple health care disciplines including urology, nursing, physical and occupational therapy, social services, and others can be extremely helpful. The psychological and emotional needs of the patient and caregivers should also be considered (Farage et al, 2008; Gotoh et al, 2009). Development of UI can be particularly stressful for older adults who may already have substantial other requirements (deVries et al, 2012). Particularly with patients whose care needs are significant or require extensive time, caregiver burden must be considered (Tamanini et al, 2011).

Elder Mistreatment

Mistreatment of older adults is an unfortunate but common problem that requires vigilance and a high index of suspicion for optimal diagnosis and intervention. **Screening for elder mistreatment is a responsibility of all health care providers.** In the United States and many other countries, health care providers are mandatory reporters for suspected abuse or neglect. Clinicians who report suspected elder mistreatment in good faith are typically

protected from liability or retaliation. Increasingly, urologists and other urologic health care providers are seeing older adults on an ongoing basis for treatment of chronic conditions. Therefore these clinicians may be in an excellent position to identify potential abuse and neglect among elderly patients. **A variety of types of elderly mistreatment must be considered, including physical abuse, emotional and psychological abuse, sexual abuse, financial exploitation, and neglect by caregivers or self-neglect.**

A careful history and physical examination are essential to diagnose and document suspected elder mistreatment. Ideally, the interview and examination should be conducted privately with the older adult, but this can be difficult, particularly if the patient has impairments in cognition, vision, speech, or hearing. **Providers need to be alert to potential signs of abuse or neglect** including overall appearance; poor hygiene; distractions or nervous interactions, particularly with accompanying caregivers; or social withdrawal and avoidance of questions. Other physical signs of abuse and neglect include bruises, abrasions or lacerations, or physical findings that are out of proportion to the described mechanism of injury. A careful genitourinary and pelvic examination should be performed in cases of suspected sexual abuse, and screening for sexually transmitted infections should be considered.

Identification of sexual mistreatment of older adults is particularly in the realm of urologic care. It is defined by the National Center on Elder Abuse as “nonconsensual sexual contact of any kind” (U.S. Department of Health and Human Services, 2014). Clinicians should be alert for signs and symptoms of sexual abuse including genital lacerations or other injuries, unusual or unexpected infection patterns including sexually transmitted infections, and avoidance behavior or fear on the part of the patient. Changes from prior observed behavior may be particularly noticeable if the clinician has been following an older adult patient longitudinally over time.

UI has been identified as a risk factor for increased rates of psychosocial abuse against elderly people (Garre-Olmo et al, 2009). Increased rates were also noted in those with depression and social isolation, conditions that are often associated with incontinence. **UI has been identified as a risk factor for neglect of older**

adults by their caregivers (Heath et al, 2005). Self-neglect by older adults is also a common but frequently undiagnosed problem. **Increased rates of self-neglect have been associated with higher levels of self-reported disability and impairments in baseline physical function (Dong et al, 2009).** The question of whether successful treatment of UI among older adult patients will help prevent or reduce rates of associated abuse and neglect deserves additional research attention.

END-OF-LIFE CARE AND UROLOGY

Palliative and end-of-life care is an important part of urologic health for many older adults. Some of the urologic malignancies may progress to a point where palliative care is appropriate. **When cure of the condition is no longer possible, treatment can shift to a palliative care mode. This does not mean that all treatment is withdrawn or that it is less focused or intense than curative therapy. Indeed, aggressive symptom management is one of the hallmark goals of palliative care** for most patients. Urologists and other urologic health care providers play a key role in the care of patients at the end of life who have genitourinary disorders.

Important aspects of high-quality palliative care include pain and symptom management, realization of personal goals for the patient and family, and coordination of care (Agar et al, 2009). Surgical therapy may play a role in select cases where cytoreductive therapy for a large tumor burden or removal of tumor for intractable bleeding or pain may help to relieve symptoms. In some cases, urinary or bowel diversion may be indicated for this purpose. Selective radiation therapy for painful bone metastases may be useful. Treatment is highly selective and tailored specifically to the needs of each individual patient. Integrated health care delivery models that include providers from multiple disciplines are feasible and can help to improve the delivery of care in these circumstances (Bergman et al, 2014). Among older adults in assisted living facilities, use of hospice services has been shown to reduce need for nursing home or other institutional placement (Dobbs et al, 2012). This can allow patients to remain living at home as long as possible

KEY POINTS

- Patient-centered care is a main focus in geriatrics, and evaluation and treatment should be tailored to meet the needs and goals of each individual. This includes consideration of family and caregiver needs.
- Multiple biologic processes contribute to the phenomenon of normal aging.
- Human aging affects the structure and function of all organ systems, including the genitourinary system.
- The elderly population is growing at a very rapid pace both in the United States and in most developed countries worldwide.
- Decreased functional reserve capacity and increased comorbidity are common with aging and strongly influence clinical outcomes.
- In addition to considering overall health status, functional assessment in geriatric patients includes evaluation of ADLs, IADLs, mobility, cognition, and other health domains.
- Comorbidity and changes in functional status tend to be stronger predictors of clinical outcomes in older adults compared with chronologic age.
- Careful optimization of medical conditions before surgery or other treatment may help improve clinical outcomes and reduce complications in geriatric urology patients.
- Geriatric syndromes are complex, multifactorial conditions that can negatively affect elderly patients. Examples include frailty, falls, pressure ulcers, polypharmacy, delirium, and UI.
- Transient UI is common in older adult patients and can be caused by many different factors. Successful treatment of the underlying condition will often help to improve or resolve the incontinence.
- Established UI is associated with substantial negative effects in elderly patients such as depression, limitation of activities, and social isolation. Evaluation and treatment plans should be individualized and can help to improve or resolve symptoms in many cases.
- Lower urinary tract and bowel dysfunction including BOO, UAB, urinary retention, nocturia, and FI are common in geriatric patients.
- POP can be successfully treated in many elderly women through use of both surgical and nonsurgical methods.
- Asymptomatic bacteriuria in geriatric patients does not usually require antibiotic therapy and needs to be differentiated from symptomatic UTI.
- Almost all of the genitourinary malignancies have higher incidence and prevalence with advancing age.
- Sexuality remains an important part of overall and health-related QoL for most older adults. Symptoms of sexual dysfunction may be signs of other underlying comorbidity such as heart disease, diabetes, or neurologic conditions.
- Urologists and urologic health care providers can play a key role in identifying elder mistreatment and neglect.
- High-quality palliative and end-of-life care is an important part of geriatric urology practice.

and can increase QoL outcomes in this setting. Consultation with trained, dedicated palliative care specialists can be extremely helpful in providing necessary care for older adults near the end of life.

SUMMARY

The aging process can have substantial effects on the genitourinary system in both men and women. Care for older adult patients needs to be tailored to their specific requirements based on a careful assessment and understanding of overall health and comorbid conditions. **Many clinical conditions seen in the specialty of urology occur with greater incidence and prevalence in elderly patients. In some ways, this makes urology by definition a geriatric specialty.** Some facets of urologic care differ significantly between elderly and younger patients. **Clinical principles of geriatrics are not always intuitive, and the body of evidence related to care for elderly patients is growing rapidly.** Additional research and education on these topics will help enhance our ability to provide high-quality care for the older adults whom we serve.

General Considerations

Urogynecologic Fistulae

Uroenteric Fistulae

Urovascular Fistulae

Other Urinary Fistulae

A fistula represents an extra-anatomic communication between two or more epithelial- or mesothelial-lined body cavities or the skin surface. Although most fistulae in the industrialized world are iatrogenic, they may also occur as a result of congenital anomalies, malignancy, inflammation and infection, radiation therapy, iatrogenic (surgical) or external tissue trauma, ischemia, parturition, and a variety of other processes. The potential exists for fistula formation between a portion of the urinary tract (i.e., kidney, ureters, bladder, and urethra) and virtually any other body cavity, including the chest (pleural cavity), gastrointestinal (GI) tract, lymphatics, vascular system, genitalia, skin, and reproductive organs. Classification is generally based on the organ of origin in the urinary tract and the termination point of the fistula (e.g., vagina, skin, GI tract). The presenting symptoms and signs are variable and depend to a large degree on the involved organs, the presence of underlying urinary obstruction or infection, the size of the fistula, and associated medical conditions such as malignancy.

GENERAL CONSIDERATIONS

Acquired urinary fistulae in the industrialized world are almost universally unexpected and may result in a great deal of inconvenience, discomfort, and physical disability for the affected individual. They are most often acquired as a result of a medical or surgical intervention for an unrelated problem, and, consequently, considerable emotional and psychologic distress often accompanies the diagnosis and subsequent treatment. As a result, not infrequently, the medicolegal aspects of these cases can be very disturbing to the treating health care practitioner, with an increasing proportion of these cases being adjudicated in court (Thomas and Williams, 2000). Nevertheless, minimizing patient discomfort, maintaining a positive and honest patient-physician relationship while providing constant reassurance, and, finally and perhaps most important, pursuing expeditious and successful treatment of the fistula will most often result in a satisfactory, nonconfrontational, mutually satisfying long-term outcome.

Notably, after the initial diagnosis of a urinary fistula, which results in external urinary leakage, immediate management or control of the urinary leakage is vital. Addressing this quickly will reduce skin breakdown and related complications, as well as alleviate much of the psychologic distress on the part of the affected individual. The judicious use of catheters, pads, and appliances can be very helpful in this regard. Skin care and odor control products are also adjunctive measures in minimizing patient-related distress until definitive therapy and repair of the fistula can be undertaken. These simple measures can often deflect or assuage the anger of an

otherwise very disaffected patient, thereby reducing the potential for further aggravating an already difficult medical and, possibly, litigious situation.

The principles of repair of urinary fistulae are outlined in Box 89-1 and can be applied to virtually any type of fistula involving the urinary tract. Prevention of urinary fistulae is, of course, paramount; however, nutrition, infection, and malignancy are important considerations not only when assessing a patient for the risk of creation of a fistula during any given intervention, but also during an evaluation for the repair of an existing urinary fistula. Although the vast majority of urinary fistulae in the industrialized world occur in healthy, well-nourished individuals, a nutritional assessment may be an important factor in some patients with fistulae, such as those patients with malignancies. Ensuring adequate nutrition is integral to surgical healing in general, but is especially important in the setting of a urinary fistula. Not uncommonly, the catabolic processes contributing to the lack of healing, which may have been a contributing factor in the initial fistula formation, are often ongoing. This is especially relevant in fistulae related to radiation therapy or in debilitated patients.

Although some types of urinary fistulae will heal with conservative management, surgery often assumes a role in the definitive repair. Repair and reconstruction of urinary fistulae are sometimes complex. These should be approached on a case-by-case basis, because repair may involve some innovative and even improvisational maneuvers in the operating room. The surgeon should be familiar with a variety of approaches and techniques, because one approach will not be optimal for all patients with a given type of urinary fistula. Principles of surgical management of urinary fistulae are outlined in Box 89-2. The finding of a persistent fistula after presumably definitive treatment may suggest the existence of other contributing host factors, such as malignancy, nutritional issues, the possibility of an unrecognized foreign body, tissue ischemia, or surgical factors such as inadequate postoperative urinary drainage, persistent distal urinary obstruction, or technical problems with the surgery.

KEY POINTS: PRESENTATION

- Urinary fistulae are often associated with considerable physical and psychologic distress for the patient and can have medicolegal consequences.
- Nutrition, infection, malignancy, urinary obstruction, and the presence of a foreign body are all important factors to consider in the initial approach to urinary fistula and in those patients in whom primary therapy has failed.

Figure 89-1. Voiding cystourethrogram demonstrates filling of the vagina (arrows) with voiding as a result of a posthysterectomy vesicovaginal fistula.

Figure 89-2. Posthysterectomy vesicovaginal fistula (VVF). Retraction with a weighted speculum and Heaney right-angled retractors to provide lateral retraction are needed to visualize this posthysterectomy VVF in a nulliparous woman.

BOX 89-1 Principles of Urinary Fistula Management

- Ensure adequate nutrition.
- Eliminate infection.
- Achieve unobstructed urinary drainage and/or stenting.
- Remove or bypass distal urinary obstruction.
- Beware of malignant cause of fistula.

BOX 89-2 Principles of Surgical Repair of Urinary Fistula

- Adequate exposure of the fistula tract with debridement of devitalized and ischemic tissue
- Removal of involved foreign bodies or synthetic materials from region of fistula, if applicable
- Careful dissection and/or anatomic separation of the involved organ cavities
- Watertight closure
- Use of well-vascularized, healthy tissue flaps for repair (atraumatic handling of tissue)
- Multiple-layer closure
- Tension-free, nonoverlapping suture lines
- Adequate urinary tract drainage and/or stenting after repair
- Treatment and prevention of infection (appropriate use of antimicrobials)
- Maintenance of hemostasis

Etiology and Prevalence

The etiology of VVF differs in various parts of the world. In the developing world, VVF is the most common fistula (>75%) (Tebeu et al, 2012) and occurs mainly from obstetric complications. In the industrialized world, the most common cause (>75%) of VVF is injury to the bladder at the time of gynecologic, urologic, or other pelvic surgery (Symmonds, 1984; Lee et al, 1988; Tancer, 1992). Surgical injury to the lower urinary tract most commonly occurs in the setting of hysterectomy (Fig. 89-2), whereas most of the remainder are related to general surgical procedures in the pelvis, anterior colporrhaphy or cystocele repair, anti-incontinence surgery, or other urologic procedures (Armenakas et al, 2004). At the Zekai Tahir Burak center in Turkey, 25,998 gynecologic and obstetric operations were performed over a 3-year period. The bladder was the most frequently injured organ. Urinary tract injury rates were reported to be 0.49% for the bladder and 0.24% for the ureter in gynecologic operations, and 0.18% for the bladder and 0.01% for the ureter in obstetric operations (Ozdemir et al, 2011). Of 207 VVFs repaired at the University of California–Los Angeles (UCLA) over a 10-year period ending in 2001, Eilber and colleagues (2003) reported the cause as abdominal hysterectomy in 83%, vaginal hysterectomy in 8%, radiation in 4%, and miscellaneous in 5%. In 1964, other causes of VVF in the industrialized world include malignancy, pelvic radiation, and obstetric trauma (including forceps lacerations and uterine rupture) (Everett and Mattingly, 1956; Gerber and Schoenberg, 1993). The use of vaginal mesh for prolapse repair may also result in VVF (Margulies et al, 2008; Ridgeway et al, 2008). Although fortunately uncommon during labor, approximately 22% of uterine ruptures are associated with a bladder injury (Raghavaiah and Devi, 1975). However, obstructed labor and obstetric trauma, in general, now account for very few VVFs in industrialized nations, probably because of the widespread availability of excellent prenatal and perinatal obstetric care.

The rate of iatrogenic bladder injury during abdominal hysterectomy is estimated to be between 0.5% and 1.0% (Keettel et al, 1978). Mathevet and colleagues (2001) reported the incidence of bladder injury during vaginal hysterectomy to be 1.7% in 3076 cases, with all injuries being recognized and repaired intraoperatively. Despite the immediate intraoperative repair reported in this series, there were four VVFs noted, giving a crude VVF rate during vaginal hysterectomy of 0.13%. The reported incidence of intraoperative bladder injury varies considerably in the literature,

UROGYNECOLOGIC FISTULAE

Vesicovaginal Fistula

Vesicovaginal fistula (VVF) is the most common acquired fistula of the urinary tract (Gerber and Schoenberg, 1993) and has been known since ancient times (Fig. 89-1).

Please see the Expert Consult website for further details.

However, it was not until 1663 that Hendrik von Roonhuyse first described surgical repair of VVF by denuding the fistula margins and then reapproximating them with sharpened stiff swan quills (Margolis and Mercer, 1994). Johann Fatio is generally credited with the first successful VVF repair, in 1675, using von Roonhuyse's technique (Falk and Tancer, 1954). In 1838, using leaden suture, John Peter Mettauer was the first U.S. surgeon to claim a successful VVF closure (Kight, 1967). In 1852, James Marion Sims published his now famous surgical series describing his method of surgical treatment of VVF using silver wire in a transvaginal approach (Sims, 1852). Of note, it was not until his 30th attempt at closure of VVF that he achieved success. However, **Sims remains the subject of considerable debate regarding his ethics** (Richardson, 1994; Sartin, 2004), because it is unknown whether the patients in his surgical series were willing and consenting participants (all were African-American slaves in pre-Civil War America). He was later to become one of the great figures in the history of operative gynecology. **The first successful transabdominal approach to VVF repair was reported by Trendelenburg in 1888, and the concept of an interpositional flap was first proposed and reported in 1928 by Martius, who used a labial fat pad.** Before 1900, the most common cause of VVF in the United States was obstructed labor (Stothers et al, 1996).

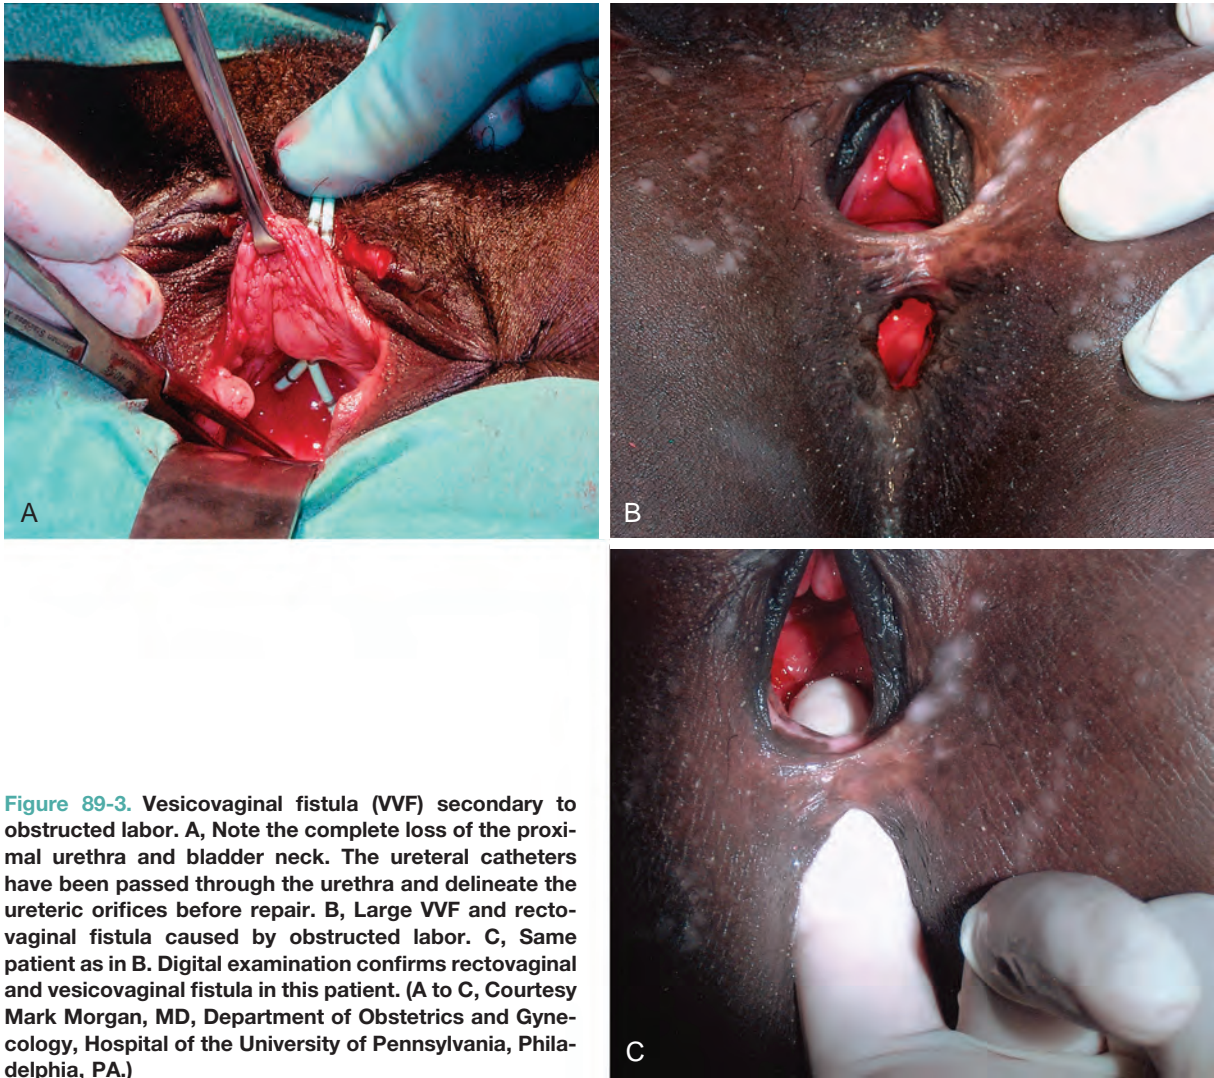

Figure 89-3. Vesicovaginal fistula (VVF) secondary to obstructed labor. **A**, Note the complete loss of the proximal urethra and bladder neck. The ureteral catheters have been passed through the urethra and delineate the ureteric orifices before repair. **B**, Large VVF and rectovaginal fistula caused by obstructed labor. **C**, Same patient as in **B**. Digital examination confirms rectovaginal and vesicovaginal fistula in this patient. depending on whether routine cystoscopy was performed. In series in which cystoscopy was not performed, the overall rate of bladder injury was reported to be approximately 2.6 per 1000 cases, whereas in series in which cystoscopy was routinely performed, the overall rate of bladder injury was approximately 10.4 per 1000 cases (Gilmour et al, 1999). The incidence of fistula after hysterectomy is estimated to be approximately 0.1% to 0.2% (Harris, 1995). There are approximately 140 to 150 VVF repairs annually in England and Wales (Hilton, 1997).

Posthysterectomy VVFs are thought to result most commonly from an incidental unrecognized iatrogenic cystotomy near the vaginal cuff (Kursh et al, 1988). If unrecognized intraoperatively, a pelvic urinoma may develop and ultimately drain out through the vaginal cuff. Ongoing urinary drainage along this tract results in a fistula. Other potential mechanisms for posthysterectomy VVF include tissue necrosis from cautery, a suture placed through both the bladder and vaginal wall during closure of the vaginal cuff, or an attempt to control pelvic bleeding by suture ligation. Tissue ischemia and then necrosis promotes fibrosis and induration, finally resulting in an epithelial or mucosal lining of the tract and the development of a fistula tract. Possibly, factors other than an isolated suture placed through the bladder and vagina are necessary for posthysterectomy VVF formation because, at least in an animal model, deliberate suture fixation of the bladder to the vagina does not invariably result in VVF in the absence of infection, urinary extravasation, or other complicating factors (Meeks et al, 1997).

In the developing world, where routine perinatal obstetric care may be limited, VVF most commonly occurs as a result of prolonged obstructed labor resulting from cephalopelvic disproportion, with resulting pressure necrosis to the anterior vaginal wall, bladder, bladder neck, and proximal urethra from the baby (Arrowsmith et al, 1996) (Fig. 89-3). The constellation of problems resulting from obstructed labor is not limited to VVF and has been termed the *obstructed labor injury complex* and includes varying degrees of each of the following: urethral loss, stress incontinence, hydroureteronephrosis, renal failure, rectovaginal fistula, rectal atresia, anal sphincter incompetence, cervical destruction, amenorrhea, pelvic inflammatory disease, secondary infertility, vaginal stenosis, osteitis pubis, and foot drop (Arrowsmith et al, 1996). The obstructed labor injury complex occurs largely in developing countries in certain cultures as a result of several factors, including (1) marriage and conception at a very young age, which results in childbearing in a relatively small and immature pelvis, (2) poor nutrition resulting in stunted skeletal (e.g., pelvic) growth in the mother, and (3) relative absence of qualified prenatal and obstetric care (Margolis and Mercer, 1994). Patients may experience obstructed labor for days in a rural environment, eventually traveling to a distant health care facility only to have a stillborn fetus and a VVF. In direct contradistinction to the epidemiology of VVF in the industrialized world, 96.5% of 932 VVFs seen at a single hospital in Nigeria over a 7-year period were temporally associated with labor and delivery (Wall et al, 2004). In a large study in Ethiopia, a total of 14,070 women of reproductive

age were included in a survey. Among women who had ever given birth (9713), some 103 experienced obstetric fistula in their lifetime, which means 10.6 per 1000 women who ever gave birth. It is estimated that in Ethiopia nearly 142,387 patients with obstetric fistula exist. Those women who are circumcised had higher odds of reporting the condition. Women who gave birth 10 or more times had higher odds of developing obstetric fistula than women with 1 to 4 children (Biadgilign et al, 2013). The incidence of obstetric fistula in developing countries has been estimated at approximately 0.3% to 0.4% of deliveries (Margolis et al, 1994), or 1 to 4 per 1000 vaginal deliveries (Margolis et al, 1994; Danso et al, 1996). In sub-Saharan Africa the incidence rate has been estimated at 10.3 per 100,000 deliveries (Vangeenderhuysen et al, 2001). An estimate of up to 500,000 new cases of obstetric fistula occur throughout the world annually (Hilton, 2003), although the total morbidity from obstructed maternal labor has been estimated to be in excess of 5 million individuals annually (Kelly, 1991). Risk factors include young or old maternal age and primigravid status (Danso et al, 1996).

Obstetric fistulae tend to be larger and located distally in the vagina and may involve large portions of the bladder neck and proximal urethra. Even in experienced hands, these are often very difficult to repair because of the extensive soft-tissue loss, as well as the ischemia and fibrosis of adjacent tissues (Arrowsmith, 1994; Elkins, 1994). Obstetric fistulae are devastating injuries in the developing world, with significant socioeconomic ramifications (Donnay and Weil, 2004; Wall et al, 2004). The affected individuals, commonly young teens, are often ostracized and shunned by family and friends and become permanent outcasts in society. Only rarely are these individuals able to get adequate care and repair because of the lack of organized health care in many countries in the developing world. Major efforts are under way to improve education, the socioeconomic status of women, and access to health care in these regions (Tahzib, 1983, 1989; Kelly, 1991; Wall, 1996; Donnay and Weil, 2004; Kelly, 2004). With improvements in the delivery of prenatal care in some areas of the developing world, it appears that the incidence of VVF from obstetric causes may be decreasing as a subset of all VVF, with a proportional increase in the rate of iatrogenic gynecologic fistulae approaching that in industrialized nations (Ayhan et al, 1995; Obi et al, 2008). Another important cause of VVF in some parts of the world is traditional folk treatments such as "gishiri cutting," which may account for up to 13% of VVFs in some series (Tahzib, 1983). This ritual practice involves using a knife to incise the anterior vagina as a treatment for a variety of conditions, including infertility, dyspareunia, dysuria, and back pain.

Other causes of VVF include urologic or gynecologic instrumentation, including percutaneous procedures (Ramsay et al, 1992; Pruthi et al, 2000); retroperitoneal, vascular, or pelvic surgery; infectious and inflammatory diseases (Borjas and Rodriguez Diaz, 1949; Bland and Gelfand, 1970; Ba-Thike et al, 1992; Monteiro et al, 1995); foreign bodies (including neglected pessaries) (Binstock et al, 1990; Goldstein et al, 1990; Grody et al, 1999); congenital VVF (Rousseau et al, 1996); sexual trauma (Roy et al, 2002); vaginal laser procedures (Colombel et al, 1995); and external violence (Box 89-3). The three most common locally advanced malignancies that result in VVF include cervical, vaginal, and endometrial carcinoma, which in aggregate account for approximately 3% to 5% of VVFs in the industrialized world. Treatment of vaginal cancer is associated with a high complication rate; up to 30% of patients develop significant complications including rectovaginal fistula or VVF, grade III to IV proctitis, cystitis, and vaginal stricture (Gunderson et al, 2013).

VVFs caused by radiation therapy deserve special mention. These VVFs may occur several decades after completion of the radiation (Zoubek et al, 1989). The incidence of urinary fistula after radiation therapy varies with the type, dose, and location of the radiation. Both external beam and interstitial (Aristizabal et al, 1983) radiation therapy may result in VVF. An incidence of 1.6% of any type of urinary fistula was noted in one series of more than 2200 patients treated with a variety of different radiation modalities

BOX 89-3 Etiology of Vesicovaginal Fistula

Traumatic

Postsurgical

- Abdominal hysterectomy
- Vaginal hysterectomy
- Anti-incontinence surgery
- Anterior vaginal wall prolapse surgery (e.g., colporrhaphy)
- Vaginal biopsy
- Bladder biopsy, endoscopic resection, laser therapy
- Other pelvic surgery (e.g., vascular, rectal)
- External trauma (e.g., penetrating, pelvic fracture, sexual)

Radiation therapy

- Advanced pelvic malignancy
- Infectious or inflammatory cause

Foreign body

Obstetric

- Obstructed labor
- Forceps laceration
- Uterine rupture
- Cesarean section injury to bladder

Congenital

for cervical carcinoma (Alert et al, 1980). In a series of 10,709 women treated by telebrachytherapy (67.5 Gy) for a range of gynecologic cancers in one center over a 22-year period, 133 (1.2%) developed urologic complications, of whom 35 (0.3%) developed fistulae (Maier et al, 1997). Perez reported a 0.6% to 2.0% incidence of VVF formation in 1456 patients undergoing combined external beam radiotherapy and brachytherapy for stages I to III cervical cancer (Perez et al, 1999). In a series of 2096 patients undergoing therapy for cervical cancer, there was an overall genital fistula rate of 1.8%, including rectovaginal fistulae. All patients diagnosed with fistula had received radiation therapy, and the median interval from completion of radiation to presentation of VVF was 8.7 months (Emmert and Kohler, 1996). Higher radiation doses seem to correlate with a greater risk for overall morbidity, as well as fistula formation (Perez et al, 1984, 1999). The endarteritis resulting from the radiation therapy may involve the surrounding tissues, limiting reconstructive options. An important consideration in any fistula after radiation therapy for malignancy is the possibility that the fistula represents a recurrence of the malignancy. Therefore biopsy of the fistula tract should be strongly considered before considering definitive repair in these patients.

Intraoperative Risk Factors for Iatrogenic Vesicovaginal Fistula

Clearly, intraoperative injury to the urinary bladder is a primary risk factor for subsequent development of a postoperative VVF. Other risk factors for postoperative VVF formation include prior uterine surgery (cesarean section), endometriosis, infection, diabetes, arteriosclerosis, pelvic inflammatory disease, and prior radiation therapy (Blandy et al, 1991; Likic et al, 2008). The American Association for the Surgery of Trauma (AAST) grade of the bladder trauma is the strongest predictor of subsequent VVF formation. Two of 3 patients developing a VVF had a grade V injury, compared with only 1 of 48 who did not develop a VVF. A grade V bladder injury as defined by the AAST involves injury to the trigone. It postulated that the proximity of the injury to the vaginal cuff serves as an avenue for VVF formation because the site of the bladder injury comes in direct contact with the healing cuff (Duong et al, 2011). The operative approach to hysterectomy is an important factor, because bladder injuries are at least three times more

common during abdominal hysterectomy compared with vaginal hysterectomy. Intraoperative recognition and repair of bladder injury are paramount in prevention of VVF; however, despite intraoperative repair, VVF may still occur in a substantial number of patients. In 1969, Hutch emphasized five factors in the prevention of VVF during gynecologic surgery: (1) immediate detection of bladder injury using vital dyes if necessary; (2) watertight closure of the bladder; (3) satisfactory extravesical drain placement; (4) avoidance of a vaginal incision, if possible, after recognition of the bladder injury; and (5) prolonged, uninterrupted postoperative bladder drainage (Hutch and Noll, 1970).

Clinical Features

Evaluation and Diagnosis. VVF must be distinguished from urinary incontinence from other causes, including stress (urethral) incontinence, urge (bladder) incontinence, and overflow incontinence, as well as ureterovaginal fistula.

Presentation. The most common complaint in patients with VVF is constant urinary drainage per vagina. The amount of urinary leakage can vary considerably from patient to patient and may be proportional to the size of the fistula tract. Patients may void a variable amount, depending on the size of the fistula and the volume of urinary leakage. For example, when a large VVF is present, patients may not void at all and simply have continuous leakage of urine into the vagina. Small, pinpoint fistulae may cause intermittent wetness, which is positional in nature. In the supine position, when sleeping, the amount of leakage reported by the patient may be minimal, but on rising to a seated or standing position the amount of leakage may increase precipitously. Patients may also report recurrent cystitis, perineal skin irritation from constant wetness, vaginal fungal infections, or rarely pelvic pain. In fact, pain is an uncommon finding in patients with VVF unless there is considerable skin irritation or the VVF occurred as a result of radiation therapy.

VVF after hysterectomy or other surgical procedures may manifest after removal of the urethral catheter, or VVF may be seen 1 to 3 weeks later with urinary drainage per vagina. It may be possible to identify some patients at high risk for VVF in the immediate postoperative period. Kursh and colleagues (1988) noted that patients who developed VVF after hysterectomy more commonly had postoperative ileus, hematuria, bladder irritability, and elevated white blood cell count compared with a cohort of patients who did not develop VVF. Occasionally, posthysterectomy VVF may go undiagnosed for an extended period of time, because postoperative clear or serosanguineous vaginal discharge is often attributed to the surgery itself.

As noted previously, VVF resulting from radiation therapy may not manifest for months to years after completion of radiation. These VVFs tend to represent very challenging reconstructive cases owing to the size and complexity of the fistula, the poor quality of the surrounding tissues, and the associated voiding dysfunction resulting from the radiation effects on the urinary bladder.

Physical Examination. A pelvic examination with a speculum should always be performed in the evaluation of VVF. The bivalved speculum examination usually provides a precise assessment of VVF including the location, size, and number of fistulae. Vaginoscopy has been suggested as an adjunct measure, in some cases, using a modified endoscope to precisely visualize the fistula tract (Redman, 1990). Today vaginoscopy using a flexible cystoscope makes it easier to visualize the fistula, particularly with a dye in the bladder. Most commonly, VVFs after hysterectomy are located along the anterior vaginal wall at the level of the vaginal cuff (Fig. 89-4). A visual and manual assessment of inflammation surrounding the fistula is necessary, because it may affect timing of the repair. Significant inflammation, infection, or induration around the fistula may mitigate against immediate repair. Relevant vaginal anatomy, including depth, associated prolapse, atrophy, and introital size are carefully recorded, because these may affect the surgical approach to repair. Anatomically, fistulae located high in the vagina, at the level of the hysterectomy cuff in a deep narrow

Figure 89-4. Vesicovaginal fistula (VVF) on physical examination. A large VVF is seen at the apex of the vagina after hysterectomy. The VVF in this image is seen as reddish pink bladder mucosa prolapsing into the vagina. Handheld Heaney right-angled retractors provide lateral retraction in this image.

vagina, may be best approached by some surgeons abdominally because a vaginal approach in these patients can be challenging. This may be especially relevant in nulliparous females in whom there is usually very limited pelvic floor laxity or vaginal prolapse. Postmenopausal vaginal atrophy may be treated with preoperative topical estrogen replacement, thereby optimizing the health and vascularity of potential reconstructive flaps. Palpation for masses or other pelvic pathology, which may require attention at the time of fistula repair, is also performed. Notation of prior incisions in the perineum, lower abdomen, and thigh is necessary because these tissues may be required for flap reconstruction when definitive repair is undertaken.

The presence of a VVF may be confirmed by instilling a vital blue dye into the bladder per urethra and observing whether vaginal drainage is discolored. Small or occult fistulae may be identified in this fashion (Drutz and Mainprize, 1988). A colored solution, such as methylene blue or indigo carmine, is mixed into solution and infused into the bladder. The vagina may be packed with gauze or directly inspected for blue-tinged leakage. If blue-tinged leakage is not apparent and the diagnosis of VVF is in doubt, the sensitivity of this test may be improved by placing a vaginal packing and ambulating the patient for a short period of time. Staining at the introital (distal) end of the packing suggests urinary incontinence or a urethrovaginal fistula, whereas proximal staining suggests a VVF. If the vaginal packing remains dye-free with this maneuver, then the possibility of a ureterovaginal fistula can be investigated with the use of clean vaginal packing, intravenous indigo carmine (or other vital dye), and a repeat pad test. Blue staining at the proximal end of the pad after this maneuver suggests the presence of a ureterovaginal fistula.

A double dye or tampon test may confirm the diagnosis of urinary fistula, as well as suggesting the possibility of an associated ureterovaginal or urethrovaginal fistula (Moir, 1973; Raghavaiah, 1974). In one variation of the double dye test, a tampon is placed per vagina. Oral phenazopyridine is administered, and vital blue dye is instilled into the bladder. If the tampon is discolored yellow-orange at the top, it is suggestive of a ureterovaginal fistula. Blue discoloration in the midportion of the tampon suggests VVF; whereas blue staining at the bottom suggests a urethrovaginal fistula.

Clear vaginal discharge after hysterectomy does not invariably represent a urinary fistula or incontinence. Other than normal

vaginal secretions, less common causes include a peritoneovaginal fistula (Ginsberg et al, 1998), lymphatic fistula (Lau and Wong, 1994), vaginitis, and fallopian tube fluid (Leach et al, 1987). Incontinence after cesarean section, in which a VVF has been excluded, may suggest the possibility of a ureterovaginal or vesicouterine fistula.

Cystoscopy. An endoscopic examination should be performed in patients for whom a suspicion of VVF is present (Fig. 89-5). Immature fistulae may appear as areas of localized bullous edema without distinct ostia. Mature fistulae may have smooth margins with variably sized ostia. In some cases, multiple pits and cavities along an area of the traumatized posterior bladder wall, in the setting of a small VVF, may make it difficult to identify the exact fistula tract. In these cases, a guidewire or ureteral catheter may be placed through the working channel of the cystoscope and into the fistula tract (Fig. 89-6). Visualization of the wire in the vagina confirms the exact location of the VVF on both the bladder and genital sides. Cystourethroscopy can confirm the presence of the fistula but also may reveal the size of the tract, the presence of collateral fistulae, and the location of the ureteric orifices in relation to the fistula.

Small fistulae, usually less than 3 to 4 mm in diameter, may be amenable to simple fulguration, which can be performed at the time of cystoscopy (see later discussion) (Stovsky et al, 1994). Of importance, in the setting of a prior history of pelvic malignancy, a biopsy of the fistula is often done to evaluate for the possibility of a recurrent malignancy. Fistulae located near or at the ureteric orifice may require ureteral reimplantation at the time of VVF repair. This type of requirement would usually mitigate against a completely transvaginal attempt at repair.

Imaging. A cystogram and/or voiding cystourethrogram (VCUG) and an upper tract study should be performed in patients being evaluated for a VVF. The cystogram may objectively determine the presence and location of the fistula. On filling of the bladder, contrast often begins to opacify the vagina, almost immediately confirming the presence of a VVF. VVFs are often best seen in the lateral projection (Fig. 89-7) in which the bladder and vagina are not superimposed. Often, the actual VVF tract may be visible in the

Figure 89-5. Endoscopic view of vesicovaginal fistula (VVF). This is the same patient as in Figure 89-4. The fistula is now seen from the bladder side. This VVF is large enough to allow one to see directly into the vagina (V) through the bladder (B).

Figure 89-6. Confirmation of a vesicovaginal fistula (VVF). A 4-Fr ureteral catheter traverses the fistula tract in this endoscopic photograph. The VVF is high on the posterior bladder wall, the typical location for a posthysterectomy VVF. The right ureter can be seen (arrow).

Figure 89-7. Cystogram demonstrating a vesicovaginal fistula (VVF). A, Lateral image demonstrates a posthysterectomy VVF. B, Anteroposterior view. The contrast agent is seen opacifying and outlining the vagina, superimposed on the bladder.

Figure 89-8. Lateral image during cystography demonstrates the vesicovaginal fistula tract.

lateral projection (Fig. 89-8). However, voiding images may be necessary in some patients with small fistulae to demonstrate the VVF. The slight increase in intravesical pressure that accompanies micturition is usually adequate to demonstrate even very small fistulae. It is important to note that a cystogram that fails to demonstrate a suspected VVF but lacks voiding images or post-void images should be considered nondiagnostic. During voiding, care should be taken to exclude vaginal voiding or reflux of contrast from the introital region cephalad into the vagina, which would produce a falsely positive image. An involuntary bladder contraction can be provoked with rapid filling during cystography, and if the intravesical pressure rises sufficiently, this may also be sufficient to demonstrate a VVF when the filling images of the cystogram failed to demonstrate it. In some instances, a cystogram can also permit an assessment of bladder capacity (important in the setting of prior radiotherapy), cystocele, bladder neck competence, and vesicoureteral reflux, any of which may have an impact on operative repair.

Up to 12% of postsurgical VVFs have an associated ureteral injury or ureterovaginal fistula (Goodwin and Scardino, 1980); thus, upper urinary tract evaluation is important. Intravenous urography (IVU) (Gerber and Schoenberg, 1993), or, more recently, computed tomography (CT) urography is usually sufficient for this purpose. In one series of 216 consecutive patients with VVF caused by obstructed labor, almost 50% of patients were diagnosed with an upper tract abnormality on IVU. Caliectasis was found in 71% of those affected; however, almost 10% were found to have a non-functioning renal unit (Lagundoye et al, 1976). If there is suspicion for a ureterovaginal fistula or if the distal ureter is not well seen on IVU, retrograde pyelography may be performed (Blandy et al, 1991) (Fig. 89-9).

In addition to contrast cystography and VCUG, CT, ultrasonography, and magnetic resonance imaging (MRI) have been used in the evaluation of VVF (Kuhlman and Fishman, 1990; Outwater and Schiebler, 1993; Yang et al, 1994). Delayed CT visualization of contrast within the vagina is considered highly suspicious for VVF in the majority of cases (Kuhlman and Fishman, 1990) (Fig. 89-10). In cases of suspected VVF, CT should be performed with only intravenous contrast, or, alternatively, a CT cystogram can be performed to isolate the bladder. A vaginal tampon placed per vagina during IVU or CT scan may improve the sensitivity for finding small or occult VVF in patients with an otherwise negative evaluation (Wesolowski and Meaney, 1977). Cross-sectional imaging may also be helpful in assessing for recurrent malignant disease in those with such a history.

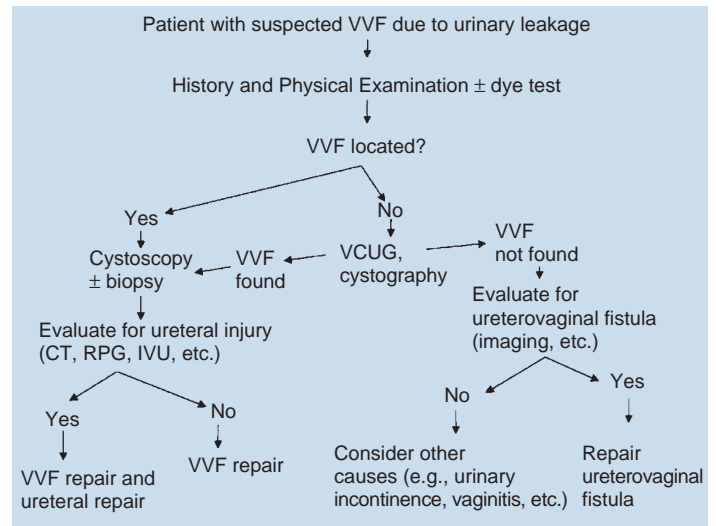

Figure 89-9. Algorithm for the diagnosis of vesicovaginal fistula (VVF). CT, computed tomography; IVU, intravenous urography; RPG, retrograde pyelography; VCUG, voiding cystourethrogram.

Other Studies. Appropriate urine studies including culture, and cytology when indicated, are performed. Urine may extravasate externally or internally. Creatinine levels in the urine are higher than serum levels. Therefore, in the setting of a suspected fistula, testing the creatinine level in either the extravasated fluid or the accumulated ascites and comparing this value to the the serum creatinine levels will confirm urinary leakage but not the location of the fistula. Likewise, testing potassium levels will show higher levels compared with serum levels (Kruger and Whiteside, 2003). When infection is detected, appropriate antibiotic coverage is initiated. Urodynamics, including video-urodynamics, are generally not necessary in the evaluation of routine posthysterectomy VVF. However, in the setting of a prior history of radiation or radical pelvic surgery (e.g., radical hysterectomy) or in those with preexisting neurogenic vesicourethral dysfunction, a urodynamic evaluation can be used to evaluate for significant detrusor dysfunction, including impaired bladder compliance.

Treatment

Conservative and Minimally Invasive Therapy. The goal of treatment of VVF is the rapid cessation of urinary leakage with return of normal and complete urinary and genital function. As noted previously, the physical and psychologic impact of constant urinary incontinence from a VVF can be overwhelming because of the burden of continual wetness, undesirable odor, vaginal and bladder infections, and their related discomfort. Bladder catheterization may temporize some of these effects until definitive repair is undertaken but often will not completely eradicate leakage, especially in those with a large fistula or those with significant detrusor overactivity. Furthermore, catheterization may provoke additional irritation and pelvic pain and is a constant reminder to the patient of an iatrogenic insult.

Regardless of the aforementioned limitations and drawbacks, a trial of indwelling catheterization and anticholinergic medication for at least 2 to 3 weeks may be warranted in selected patients with newly diagnosed VVF, because spontaneous healing may result (Davits and Miranda, 1991). The characteristic of fistulae most widely accepted for favorable outcome with conservative management is size less than 2 to 3 mm. An analysis of pooled data on 348 fistulae showed a spontaneous closure rate with catheterization of 13% ± 23% (De Ridder et al, 2013). Simple injuries to the bladder that do not involve devascularization or thermal injury spread that result in interrupted blood supply to the area have a good chance of healing conservatively. Drainage of the

Figure 89-10. Computed tomography (CT) scan of vesicovaginal fistula (VVF). A, After intravenous administration of the contrast agent, there is high-density material in both the bladder and vagina consistent with a VVF. The fistulous connection is between the bladder anteriorly and the vagina posteriorly. B, Sagittal CT reconstruction demonstrating VVF.

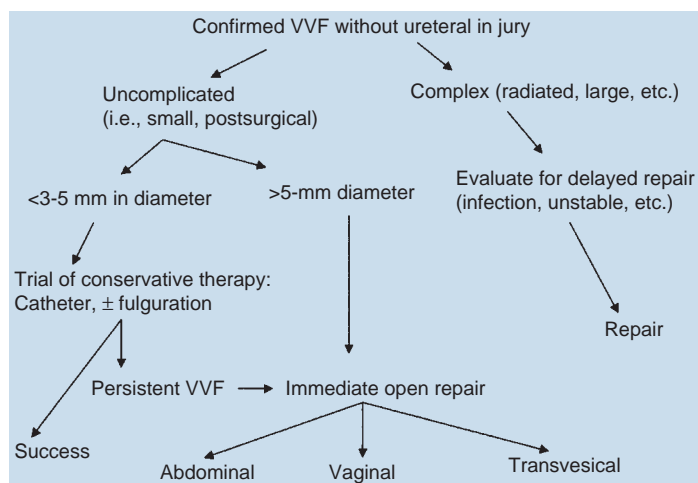

Figure 89-11. Algorithm for management of vesicovaginal fistula (VVF).

bladder should start immediately to prevent epithelialization of the fistula tract. When considering management of iatrogenic VVF, attention should be paid not only to the size of the defect, but also the period between the injury and initiation of therapy, the mechanism of injury, and patient factors such as pelvic anatomy and overall health. Patients should be counseled that conservative management may take up to several months (Wild et al, 2012). Fistulous tracts that remain open 3 or more weeks after adequate Foley drainage are unlikely to resolve without further intervention, especially those that appear completely epithelialized on examination.

Patients with small epithelialized fistulae may benefit from a minimally invasive treatment involving disruption of the epithelial layer of the fistula tract (Fig. 89-11). Catheterization may be combined with minimally invasive electrocoagulation of the fistula tract. In this approach, a small cautery electrode is passed into the fistula tract endoscopically as far as possible. The electrode is slowly withdrawn from the tract with the electrode set on coagulation. The edges of the fistula tract should blanch. This approach was advocated by O'Connor as far back as 1938 for small, highly situated

fistulae (O'Connor and Sokol, 1951) and has been reported in several small case series. Endoscopic transvesical VVF fulguration may be a safe and effective procedure for small VVFs on a day care basis, with decreased morbidity, improved cosmesis, and decreased hospital stay (Shah, 2010). Also, laser welding has been tried with success in a small series of women with fistula smaller than 3 mm (Dogra and Saini, 2011). All successfully treated patients had VVF less than 3 mm in diameter; in two patients with 6-mm VVF this approach failed. **Of importance, in patients with a thin vesicovaginal septum, large VVF, a nonoblique fistula tract, or significant inflammation around the fistula tract, fulguration risks failure and the possibility of enlarging the size of the fistula.** This approach may also devitalize adjacent tissues, thereby compromising their future use as flaps. Fibrin sealant has been used as an adjunctive measure to treat VVF (Pettersson et al, 1979; Hedelin et al, 1982). The fibrin sealant may be injected directly into the fistula tract after fulguration as described earlier. The bladder is then drained for several weeks. Presumably, the gel-like nature of the fibrin sealant plugs the hole until tissue ingrowth occurs from the edges of the fistula. Fibrin sealant has been used successfully in combination with (Morita and Tokue, 1999) and without (Evans et al, 2003b) bovine collagen as an additional "plug." **In general, these conservative measures are useful for small, oblique fistulae (usually less than 2 to 3 mm in diameter), in patients who are agreeable to this course of therapy.**

Case reports of other minimally invasive VVF repair techniques have been reported, including laser tissue welding with a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser (Dogra and Nabi, 2001), as well as transurethral endoscopic suturing (Okamura et al, 1997; McKay, 2001).

Surgical Repair. It has been stated that the best opportunity to achieve successful repair of VVF is with the initial operation (Weed, 1978; Elkins, 1994). Previous failed attempts at repair produce scarring and anatomic distortion and may compromise potential reconstructive flaps. Therefore careful preoperative planning is essential to maximize the chances for a successful result. **There is no "best" approach for all patients with VVF.**

Timing: Immediate versus Delayed Repair. The timing of VVF repair is somewhat controversial. Repair of VVF should be as expeditious as possible to minimize patient suffering; however, optimal timing for repair should allow consideration of certain medical and surgical factors as well. It is generally accepted that VVF resulting from obstructed labor should be associated with a

3- to 6-month delay before definitive repair (Wein et al, 1980a; Arrowsmith, 1994; Waaldijk, 1994) to allow maximum demarcation of ischemic tissue and resolution of the associated edema and inflammatory reaction. Longer periods of time, up to 6 to 12 months, have been advocated for radiation-induced fistulae (Wein et al, 1980a), which are often associated with severe obliterative endarteritis and reduced tissue vascularity.

In the classical teaching of VVF, a minimal waiting period of several months is suggested—from the inciting event before the definitive repair attempt—to allow reduced tissue edema and inflammation, and optimal pliability of the tissues (Persky and Rabin, 1973; Lawson, 1978; O'Connor, 1980; Wein et al, 1980a). O'Connor recommended a waiting period of 3 to 6 months for suprapubic VVF repairs (O'Connor et al, 1973). In this setting, reduced inflammation and edema permit easier identification of tissue planes (and therefore flap development), less bleeding, and less tension on the reapproximated suture lines. **There is no consensus in the literature as to the definition of "early" in this context, with different studies either failing to specify at all, or giving a broad range of definition. Although some studies have used the terms "immediate" (Lee et al, 2010), "less than 2 weeks" (Shelbaia and Hashish, 2007), or "less than 30 days" (Soong and Lim, 1997), most reports have considered either less than 6 weeks (Badenoch et al, 1987; Blandy et al, 1991; Kam et al, 2003) or less than 3 months (Wang and Hadley, 1990; Moriel et al, 1993; Shelbaia and Hashish, 2007; Radoja et al, 2010) as their definition of early intervention. Although relatively few studies have reported their outcomes for both early and late approaches to management, overall the results do not appear to be significantly different. The overall results for early management are estimated at 91% \pm 6% and for later management (where provided) 90% \pm 27% ($P = 1.00$; Fisher's exact test). The enthusiasm for delayed management has waned, and, in general, uncomplicated postgynecologic urinary fistulae may be repaired as soon as they are identified and confirmed, thereby minimizing patient discomfort and anguish (Collins et al, 1971; Persky et al, 1979; Fourie, 1983; Badenoch et al, 1987; Cruikshank, 1988; Wang and Hadley, 1990; Blandy et al, 1991; Blaivas et al, 1995; Kostakopoulos et al, 1998). This is especially true when they occur as a result of clean surgical trauma (Wang and Hadley, 1990). Nondelayed closure has also been applied to obstetric fistulae with good results (Waaldijk, 1994, 2004). Nevertheless, in some cases, the timing of a VVF repair is best tailored to the individual patient (Blaivas et al, 1995). Raz and colleagues (1993) suggested that uncomplicated VVF after**

abdominal hysterectomy could and should be repaired as expeditiously as possible transvaginally; however, a 2- to 3-month waiting period may be warranted for some VVFs after vaginal hysterectomy. Conversely, if an abdominal approach is being considered after a particularly difficult or complicated abdominal surgery that resulted in the VVF (e.g., complicated by abscess, urinoma), then a delay may be warranted to allow resolution of active inflammation. Another potential reason to delay repair is to treat ongoing infection or inflammation at the level of the vaginal cuff. Periodic reexamination of the vaginal tissues can be performed every 1 to 2 weeks, and definitive repair scheduled when suitable pliability is noted (Carr and Webster, 1996).

A vaginal approach can be attempted as soon as 2 to 3 weeks after the initial injury, if conservative therapy fails (i.e., the patient remains wet when a Foley catheter is in place to provide adequate drainage of the bladder) and the patient is in good general health. The vaginal tissues are usually relatively undisturbed from the prior causative surgery, especially if the surgery was transabdominal. Wide healthy vaginal flaps can usually be obtained. In the rare circumstance in which a VVF is seen within the first 24 to 48 hours postoperatively, an immediate repair can be attempted (Margolis and Mercer, 1994); however, it is possible that these VVFs, especially if small in diameter, may heal spontaneously with catheterization over the course of several weeks. It is well documented that similar outcomes can be achieved with early versus delayed abdominal and vaginal repair (Collins et al, 1960; Persky et al, 1979; Zimmern et al, 1985; Badenoch et al, 1987; Wang and Hadley, 1990; Blandy et al, 1991), with success rates in excess of 90% for uncomplicated VVF.

Approach: Abdominal versus Vaginal. VVF may be repaired through a transvaginal or transabdominal (transvesical) approach. Each approach has merits depending on the particular circumstances of the fistula, and excellent outcomes can be expected with both approaches (Table 89-1). Although factors such as size, location, and the need for adjunctive procedures often influence the choice of approach, the most important factor is the experience of the operating surgeon. Thus there is no preferred approach for all fistulae, and the "optimal" approach to the uncomplicated postgynecologic VVF is usually the one that is most successful in the individual surgeon's hands (Gerber and Schoenberg, 1993; Akman et al, 1999). There are no randomized studies comparing abdominal and vaginal approaches; given that surgeons undertaking both routes for repair would usually see specific indications for the two, such a comparison is most unlikely ever to be seen

TABLE 89-1 Abdominal versus Transvaginal Repair of Vesicovaginal Fistula

	ABDOMINAL	TRANSVAGINAL
Incision	Abdominal incision	Vaginal incision(s) can be done immediately in the absence of infection or other complications.
Timing of repair (elapsed time from fistula creation)	Often delayed 3-6 months.	
Exposure	Fistula located low on the trigone or near the bladder neck may be difficult to expose transabdominally.	Fistula located high at the vaginal cuff may be difficult to expose transvaginally.
Location of ureters relative to fistula tract	Fistula located near ureteric orifice may necessitate reimplantation.	Reimplantation may not be necessary even if fistula tract is located near ureteric orifice.
Sexual function	No change in vaginal depth.	Risk of vaginal shortening (e.g., Latzko technique).
Use of adjunctive flaps	Omentum, peritoneal flap, rectus abdominis flap.	Labial fat pad (Martius fat pad), peritoneal flap, gluteal skin or gracilis myocutaneous flap.
Relative indications	Large fistulae, location high in a deep narrow vagina, radiation fistulae, failed transvaginal approach, small-capacity bladder requiring augmentation, need for ureteral reimplantation, inability to place patient in the lithotomy position.	Uncomplicated fistulae, low fistulae.

as feasible, ethical, or appropriate. We have identified nine nonrandomized cohort studies reporting results from both abdominal and vaginal procedures (Demirel et al, 1993; Langkilde et al, 1999; Kam et al, 2003; Ou et al, 2004; Catanzaro et al, 2005; Ayed et al, 2006; Hadzi-Djokic et al, 2009; Ockrim et al, 2009; Hilton, 2012). In all, these series included 388 vaginal repairs and 345 abdominal repairs with overall closure rates at first operation of 89% and 87%, respectively ($P = .367$; Fisher's exact test). The same reports included 255 transvesical repairs with a 93% cure rate and 399 transperitoneal repairs with an 89% success rate ($P = 0.130$; Fisher's exact test) (De Ridder et al, 2013). Although it has been a long-held belief that gynecologists prefer to fix VVF transvaginally and urologists prefer a transabdominal approach because of their respective training and experience (Edwards, 1982; Gerber and Schoenberg, 1993), this difference is becoming increasingly blurred as urologists gain more experience and comfort operating transvaginally for a variety of disparate indications.

The vast majority of VVFs in the industrialized world are amenable to a transvaginal repair (Turner-Warwick, 1972; Margolis and Mercer, 1994). The relative advantages of a transvaginal approach compared with an abdominal approach are outlined in Box 89-4 on the Expert Consult website and include shorter operative times, briefer hospital stay, and less blood loss (Goodwin and Scardino, 1979). The principal disadvantages of the transvaginal approach include the relative lack of familiarity of the vaginal cuff anatomy to many urologists; the potential for vaginal shortening, especially with the Latzko approach; and, finally, the difficulty in exposing high or retracted fistulae located near the vaginal cuff, especially in deep, narrow vaginas, or in those without any apical prolapse, such as that found in nulliparous females (see Fig. 89-2). Patients who are unable to get into the high-lithotomy position because of musculoskeletal conditions are not candidates for a transvaginal approach.

The abdominal approach to VVF repair is advantageous in several circumstances. If the VVF is associated with other intra-abdominal pathology requiring repair—including an associated ureteral injury (i.e., ureterovaginal fistula), or a complex fistula, including those involving another intra-abdominal organ—then a transabdominal approach is indicated to address the problems simultaneously. If the VVF is located adjacent to the ureteric orifice, some authors have suggested that this is an indication for an abdominal approach (Carr and Webster, 1996), whereas others have not so advocated (Dupont and Raz, 1996). In patients with a small-capacity or poorly compliant bladder (often secondary to radiation) requiring augmentation cystoplasty, an abdominal approach is indicated, because both procedures can be performed using the same incision. Complicated fistulae, including those associated with multiple prior failed attempts at repair (Kristensen and Lose, 1994) or those that are quite large (>5 cm), might be best approached abdominally as well. Nevertheless, a prior failed attempt at repair is not necessarily a contraindication to a transvaginal approach because excellent results can be achieved in this setting (Eilber et al, 2003).

Combined transabdominal-transvaginal approaches to VVF have been described (Clark and Holland, 1975; Taylor et al, 1980; Henriksson et al, 1982). This approach may be applicable selectively in the setting of large, complex, or recurrent VVF after prior attempts at repair. Laparoscopic or robotic-assisted repair (detailed later) of fistulae located above the trigone is gaining increasing popularity because these procedures have a potential to decrease the morbidity of the open abdominal approach (Nabi and Hemal, 2001).

Handling of Fistula Tract: Excision versus No Excision. A long-held tenet for successful fistula closure, dating back to the original description by Sims in 1852, involves complete excision of the fistulous scar tissue and tract (Fearl and Keizur, 1969; Persky et al, 1979; Wein et al, 1980a; Fourie, 1983). This approach ensures clean, well-vascularized viable edges to be approximated for the initial layer of repair. Simple excision of the scar in an inverted "funnel" shape with careful reapproximation of the defective edges has been shown to be an effective repair of VVF (Iselin et al, 1998; Flynn et al, 2004). However, excision of the fistula tract itself is

not always necessary and may even compromise the repair in some patients (Zimmern et al, 1985; Cruikshank, 1988; Tancer, 1992; Raz et al, 1993; Margolis and Mercer, 1994). There is only a single randomized trial comparing aspects of surgical technique; Shaker and colleagues reported a randomized controlled trial (RCT) comparing trimming of the fistula edge with no trimming (Shaker et al, 2011). Although there was no statistical difference in success rates between the two groups, in patients in whom repair was unsuccessful and trimming had been undertaken, the fistula tended to become larger, whereas fistulae wherein there was no trimming were more likely to be smaller on recurrence. There are several potential disadvantages of excision of the fistula tract. First, this creates a larger soft-tissue defect to be repaired. Excision of the fibrous tract may lead to bleeding, which, if cautery is used, may result in tissue necrosis and impede healing (Eilber et al, 2003). If the VVF is adjacent to the ureter, then excision of the tract may mandate reimplantation of the ureter. Alternatively, if the tract is left in situ, the ureter may be catheterized for the repair and then left undisturbed during a transvaginal operation, obviating the need for reimplantation. In addition, in chronic fistulae, a strong fibrous ring forms outside the epithelialized tract, which maintains some strength through the repair if this layer is incorporated into the closure. This can be an important consideration in patients with significant detrusor overactivity postoperatively from either the repair itself or the indwelling drainage catheters.

Use of Adjuvant Flaps or Grafts: Type and Application. Before embarking on surgical repair, the surgeon should be familiar with a variety of adjuvant flaps and grafts that allow for the interposition of healthy tissue during VVF repair. It is often not possible to predict which patients will require these procedures. The indications for tissue interposition are not well defined, but these measures are most commonly used in the setting of irradiated tissues, obstetric fistulae, failed prior repairs, large fistulae, and patients with tenuous repairs. The various types of flaps are discussed in more detail later in the chapter.

Other Considerations. Preoperative estrogen supplementation may be beneficial in the postmenopausal patient with vaginal atrophy and VVF (Massee et al, 1964). There exist few data in the literature, beyond expert opinion, to support its use. However, topical estrogen preparations may improve vascularity (Margolis and Mercer, 1994) and local tissue quality (Carr and Webster, 1996). Therefore a trial of topical estrogens in individuals with postmenopausal vaginal atrophy and a posthysterectomy VVF may be warranted, provided that there are no contraindications to their use.

Perioperative intravenous antibiotics are often administered, although their usefulness in posthysterectomy VVF repair is questionable in the absence of infection. Whether antibiotics should be administered prophylactically before surgical repair is controversial, but at least one study suggests that preoperative antibiotics do not improve outcomes when administered before the repair of obstetric fistula (Tomlinson and Thornton, 1998). Treatment of existing infection based on preoperative urine culture is potentially beneficial in preventing bacteremia during surgery. However, prolonged use of broad-spectrum antibiotics postoperatively after repair may result in bacterial resistance and possibly fungal vaginal infections that may compromise suture lines.

Sexual activity should be documented preoperatively. Patients should be specifically queried regarding sexual function and dyspareunia occurring before the onset of the event that resulted in the fistula. Although this information is subject to recall bias, it may play an important role in the choice of surgical approach, as well as having medicolegal implications postoperatively. Some types of vaginal procedures for the repair of VVF, including the Latzko partial colpocleisis, may result in vaginal shortening and postoperative dyspareunia. Preoperative documentation of this preexisting condition can be invaluable. Furthermore, adjuvant procedures that may alter vaginal appearance or function, such as the harvesting of a Martius fibrofatty labial flap or an episiotomy, should be carefully discussed with the patient in advance, especially regarding sexual function.

BOX 89-4 Potential Advantages of a Transvaginal Approach for Posthysterectomy Vesicovaginal Fistula

Avoidance of a laparotomy and its associated morbidity
Short operative time
Brief inpatient stay
Quick convalescence and return to normal activities
Minimal postoperative pain
Minimal blood loss
Absence of the need for wide opening or bivalving of the bladder
Approach not compromised by multiple prior abdominal and/or pelvic surgeries
Concomitant anti-incontinence or prolapse surgery may be performed
Local interpositional flaps are adjacent (e.g., Martius, peritoneal)
A three- or four-layer closure is possible
If failure occurs, subsequent abdominal approach is not compromised

Finally, postoperative drainage after VVF repair can be maintained by single or dual catheters. Some authors suggest that a urethral catheter alone provides satisfactory drainage (Collins et al, 1960; Fearl and Keizur, 1968; Tancer, 1980; Leng et al, 1998). Others advocate a suprapubic catheter alone (Blaivas et al, 1995; Carr and Webster, 1996; Iselin et al, 1998) to minimize bladder spasms and trauma to the surgical repair. Most commonly, both urethral and suprapubic drainage catheters (O'Connor et al, 1973; Wein et al, 1980a; Dupont and Raz, 1996; Eilber et al, 2003) are left postoperatively. The disadvantage to single-catheter drainage is principally that the catheter will malfunction, clog, or kink, resulting in bladder filling, eventual overdistention, and disruption of the suture line.

Preoperative Counseling and Indications for Surgery. Surgical repair of a VVF is indicated after confirmation of the diagnosis. As noted previously, a trial of conservative management may be warranted in selected cases, especially in those with a newly diagnosed, small, uncomplicated fistula in which the vaginal leakage significantly improves or resolves with catheter drainage. When conservative measures fail or if after adequate counseling the patient requests repair before a trial of conservative management, surgical treatment is pursued. Before surgery, patients should be counseled that VVFs in the industrialized world are repaired on the first attempt in more than 90% of cases; however, prolonged postoperative urinary catheter drainage is necessary after surgery. Postoperative urinary urgency and frequency are common for a period of time after removal of the catheter but are usually self-limited. Finally, the patient should be aware that it may be necessary to alter the surgical plan intraoperatively as a result of a variety of factors encountered during the operation, and that interpositional flaps or grafts may be used.

Vaginal Techniques. Common vaginal approaches to the repair of uncomplicated VVF are described. The merits of the vaginal approach are reviewed in Table 89-1 and Box 89-4 on the Expert Consult website.

Vaginal Flap or Flap-Splitting Technique. The vaginal flap or flap-splitting approach popularized by Raz and colleagues (Zimmern et al, 1985; Raz et al, 1993; Stothers et al, 1996; Eilber et al, 2003) results in a three-layer closure without the use of an adjuvant flap, and a four-layer closure if a flap is used (Fig. 89-12). It can be performed as an outpatient procedure and is applicable to most simple, uncomplicated VVFs (Fig. 89-13).

Please see the Expert Consult website for further details.

Complications. Proper surgical technique is critical in avoiding complications. Dissection in the proper surgical planes assures minimal bleeding. When significant bleeding is encountered during the dissection, it is possible that an improper plane of dissection was entered. Careful intraoperative inspection and reevaluation of the surgical planes are warranted. Furthermore, excessive use of cautery may compromise the vascular supply of the tissue flaps used for repair. This may become evident only in the postoperative period with ischemic flaps and recurrence of the fistula. Intraoperative bleeding should be controlled with fine absorbable suture whenever possible. **The possibility of ureteral injury is a concern, if the VVF is located adjacent to the insertion of the ureter.** If there is doubt regarding a ureteral injury, then cystoscopy should be performed after the intravenous administration of indigo carmine. Blue efflux from the ureteric orifice confirms ureteral patency.

Long-term complications from transvaginal VVF repair include vaginal shortening and stenosis. Careful attention to flap mobilization and reconstruction will minimize this complication. In addition, excessive resection of the vaginal wall should be avoided during reconstruction to avoid vaginal shortening or scarring.

The most important complication of VVF repair is recurrence of the fistula. A repeat transvaginal approach can be attempted with satisfactory success. A careful review of potential factors leading to failure of the initial repair is undertaken, and any remediable factors (e.g., inadequate nutrition, vaginal atrophy, excessive postoperative bladder spasms) are addressed. Strong consideration should be given to the use of adjuvant flaps in repeat VVF repairs, in which tissue quality may be suboptimal.

Other Transvaginal Techniques. There are multiple variations to transvaginal fistula repair, including those originally described by Latzko in 1914. The Latzko high-partial colpocleisis is a very popular approach among some reconstructive surgeons, with reported success rates in excess of 90% (Kaser, 1977; Tancer, 1980). This approach may not be as successful as the vaginal flap technique for large obstetric fistulae (Elkins et al, 1988). In this procedure, the fistula tract is isolated, and the tissue surrounding the VVF tract is denuded of vaginal "epithelium" circumferentially for a distance of 1 to 2 cm. Care is taken to avoid deeply "denuding" the vaginal tissues to avoid entry into the bladder or perivesical fascia. The denuded areas are then reapproximated over the fistula tract with a series of interrupted absorbable sutures. Sutures are not placed into the bladder wall or vesical mucosa. The edges of the vaginal wall are then reapproximated as a second layer, creating a partial colpocleisis in some patients. Advantages of the Latzko procedure include minimal blood loss, no need for ureteral reimplantation (even for a fistula adjacent to the ureter, because sutures are not placed through the bladder), and a short convalescence. Potential disadvantages include the possibility of vaginal shortening (Enzelsberger and Gitsch, 1991), as well as the creation of directly overlapping suture lines.

Webster and colleagues reported excellent results with a transvaginal approach to VVF by vaginal cuff excision (Iselin et al, 1998; Flynn et al, 2004). In this approach, the fistula tract is isolated, and the entire epithelialized portion of the tract is excised in the fashion of a wide inverted cone, leaving a funnel-shaped defect from the vesical to the vaginal side of the fistula. The defect is then closed in three or four layers using absorbable suture. The principal advantages of this technique are that mobilization of vaginal flaps is not required, and vaginal shortening is minimal.

Abdominal Techniques. VVF may be repaired transabdominally, and this is the preferred approach in those cases requiring augmentation cystoplasty or ureteral reimplantation. Compared with the vaginal approach, the abdominal approach to VVF repair is associated with a longer recovery time and in-patient hospitalization, greater blood loss, more cosmetic deformity, and, in general, greater morbidity. Abdominal repair of VVF may be performed intraperitoneally or extraperitoneally, as well as transvesically.

Suprapubic Intraoperative or Extraperitoneal Approach. The patient is positioned in a low lithotomy position with access to the vagina in the sterile operative field. Ureteral catheters may be placed preoperatively or intraoperatively to assist in identification of the ureters, especially if the VVF is in close proximity to the ureteric orifices. A lower midline incision is carried out. As classically described by O'Connor and colleagues (O'Connor and Sokol, 1951; O'Connor et al, 1973), the bladder is approached extraperitoneally; however, in some cases, the peritoneum will be entered. The bladder is opened vertically, and the cystostomy is extended down to the opening of the VVF (Fig. 89-14). As the dissection proceeds distally, stay sutures placed on the bladder edges greatly assist in retraction. In addition, a curved sponge stick placed per vagina with gentle upward traction can provide excellent exposure of the VVF. With the bladder having been bivalved down to the level of the VVF, the VVF tract is excised, and the dissection is continued beyond the fistula tract to develop the vesicovaginal space (Fig. 89-15). The vagina is carefully dissected and separated from the bladder for a distance of 2 to 3 cm beyond the VVF. **The key to the operation is the mobilization of the bladder from the vagina caudal to (beyond) the VVF tract.** After wide mobilization from the bladder, the vagina is closed with a running absorbable suture. At this point, if an interpositional flap of greater omentum is to be used, it is mobilized and then secured 1 to 2 cm distally beyond the excised VVF tract (see later discussion) (Wein et al, 1980a). The bladder is then closed in several layers. A suprapubic tube and urethral catheter are usually left for postoperative drainage. Anticholinergic agents are used liberally in the postoperative period to minimize bladder irritability, which may be problematic.

Bladder augmentation or ureteral reimplantation, if necessary, can be incorporated into the suprapubic approach before closure

Step 1: Positioning, Preparation, and Retraction. The patient is placed in the dorsal lithotomy position; rectal packing is placed (to aid in identification of the rectum); and the lower abdomen and perineum are prepared with a standard surgical preparation solution. Appropriate exposure is maintained with use of a vaginal weighted speculum, silk labial retraction sutures, and a ring retractor with hooks. A suprapubic tube is placed, cystoscopy with reassessment of the VVF location is performed, and ureteral catheters are placed if the fistula tract is adjacent to or involves the ureteric orifices. A posterolateral episiotomy may be performed to improve exposure in patients with a narrow introitus. A urethral catheter is placed in addition to the suprapubic tube, maximizing postoperative urinary drainage (see Fig. 89-13A). **Any concomitant anti-incontinence or other vaginal surgery that is to be performed simultaneously with VVF repair should be done before reconstruction to avoid disturbing the repair once completed.**

Step 2: Incision. The fistula tract is cannulated with a small Foley catheter (10 to 12 Fr) and, after inflation of the balloon, gentle downward traction is placed on the Foley catheter, pulling the VVF toward the introitus. Occasionally a small VVF requires dilation with metal sounds to place the Foley catheter. To facilitate dilation of the fistula tract in these cases, a guidewire may be placed through the fistula tract endoscopically, and sequential dilation performed using Goodwin sounds. The gentle traction on the VVF provided by the Foley catheter greatly enhances exposure (see Fig. 89-8). The vaginal flaps are marked (see Fig. 89-13B). Saline is then injected into the anterior vaginal wall surrounding the fistula tract and along the lines of the vaginal flaps. The fistula tract is carefully circumscribed. An inverted J-shaped or U-shaped incision that circumscribes the fistula tract is made with the limbs of the J or U extending to the apex of the vagina. The circumscribed fistula is incorporated into the curved portion of the incision. The nature of this incision allows creation of a vaginal wall flap that can be advanced and rotated over the fistula repair. This helps avoid vaginal shortening and overlapping of suture lines during reconstruction. However, some surgeons have recommended that the long end of the incision be extended along the anterior vaginal wall toward the introitus (Wang and Hadley, 1990).

Step 3: Creation of Vaginal Wall Flaps. The vaginal wall flaps are created by dissecting in a proximal, distal, and lateral direction away from the fistula tract (see Fig. 89-13C). Initially, dissection may be difficult because of scarring from the insult that resulted in the VVF. It is important to remain in the correct surgical plane while developing the vaginal wall flaps, so as not to compromise their vascularity. Adequate mobilization of the vaginal wall distal to the VVF is especially important, because it will be necessary to advance the proximal vaginal wall flap beyond the fistula as the final layer of closure. Each flap is mobilized 2 to 4 cm from the fistula tract, exposing the underlying perivesical fascia. The ring of vaginal wall tissue, where the initial incision circumscribed the fistula opening, is left intact; thus, flap creation is done in healthy tissue, avoiding dissection of the actual fistula tract. This technique facilitates dissection in proper tissue planes, avoids bleeding edges at the resected fistula tract, ensures that closure of the fistula is done with healthy tissue (vaginal wall flaps), and decreases the risk of potential bladder perforation. Wide mobilization of the vagina off the perivesical fascia for a distance of several centimeters of bladder allows creation of a tension-free closure.

Step 4: Fistula Closure. Closure of the fistulous opening is now done. The catheter in the fistula tract is removed, and the first layer of the repair is performed. Interrupted 3-0 or 4-0 absorbable sutures are placed in a transverse or vertical fashion across the fistula. These sutures incorporate bladder wall and the fistulous tract itself, starting in healthy tissue approximately 0.5 cm away from the margin of the fistula (see Fig. 89-13D). Inclusion of the fistula tract in the repair (and not resecting the fistula) provides a strong anchor of supporting tissue for the first layer of the repair. The use of a double-armed suture, with both sides thrown from within the fistula tract outward, facilitates incorporation of good-quality tissue. The Foley catheter can be taken off traction while these sutures are placed to avoid puncturing the balloon. The second layer of the repair is placed with interrupted 2-0 or 3-0 absorbable sutures. These sutures are placed to invert the previous layer by imbricating the perivesical fascia and the deep musculature of the bladder over the first layer and fistula tract (see Fig. 89-13E). The sutures should be applied at least 3 to 5 mm from the prior suture line, free of tension, and at a 90-degree angle from the first suture line to minimize overlapping of the two lines of repair. The integrity of the repair is confirmed by filling the bladder with 200 to 300 mL of saline mixed with indigo carmine and observing for vaginal staining. At this point, if desired, an interpositional peritoneal or Martius flap may be mobilized and secured over the existing suture line (Raz et al, 1993; Eilber et al, 2003).

Step 5: Advancement and Closure of Vaginal Wall Flap. The final and third layer of closure is done with the vaginal wall flaps that were previously created. The redundant, excess anterior (distal) vaginal flap is excised, and the posterior (proximal) vaginal flap is advanced beyond the fistula closure. This covers the fistula site with fresh, healthy vaginal tissue, which helps avoid overlapping of suture lines.

Step 6: Closure of the Vaginal Wall. The flap is advanced at least 2 to 3 cm beyond the fistula closure, and the vaginal wall is closed with a running, locking, absorbable 2-0 suture. An antibiotic-impregnated vaginal packing is placed for 24 hours postoperatively. The urethral Foley and suprapubic catheters are left to drain for 10 to 14 days.

Postoperative urinary drainage is essential, and the draining catheter(s) are left in all patients postoperatively until cystography confirms successful repair of the fistula. In general, imaging is obtained 10 to 21 days from the time of repair. If a persistent leak is noted, ongoing catheterization and repeat imaging at a 2- to 3-week interval may demonstrate eventual resolution (Schwab and Rovner, 2003). Anticholinergic agents are given to decrease bladder irritability. A cystogram is done before catheter removal to document integrity of the repair. Sexual intercourse is avoided for 2 to 3 months postoperatively.

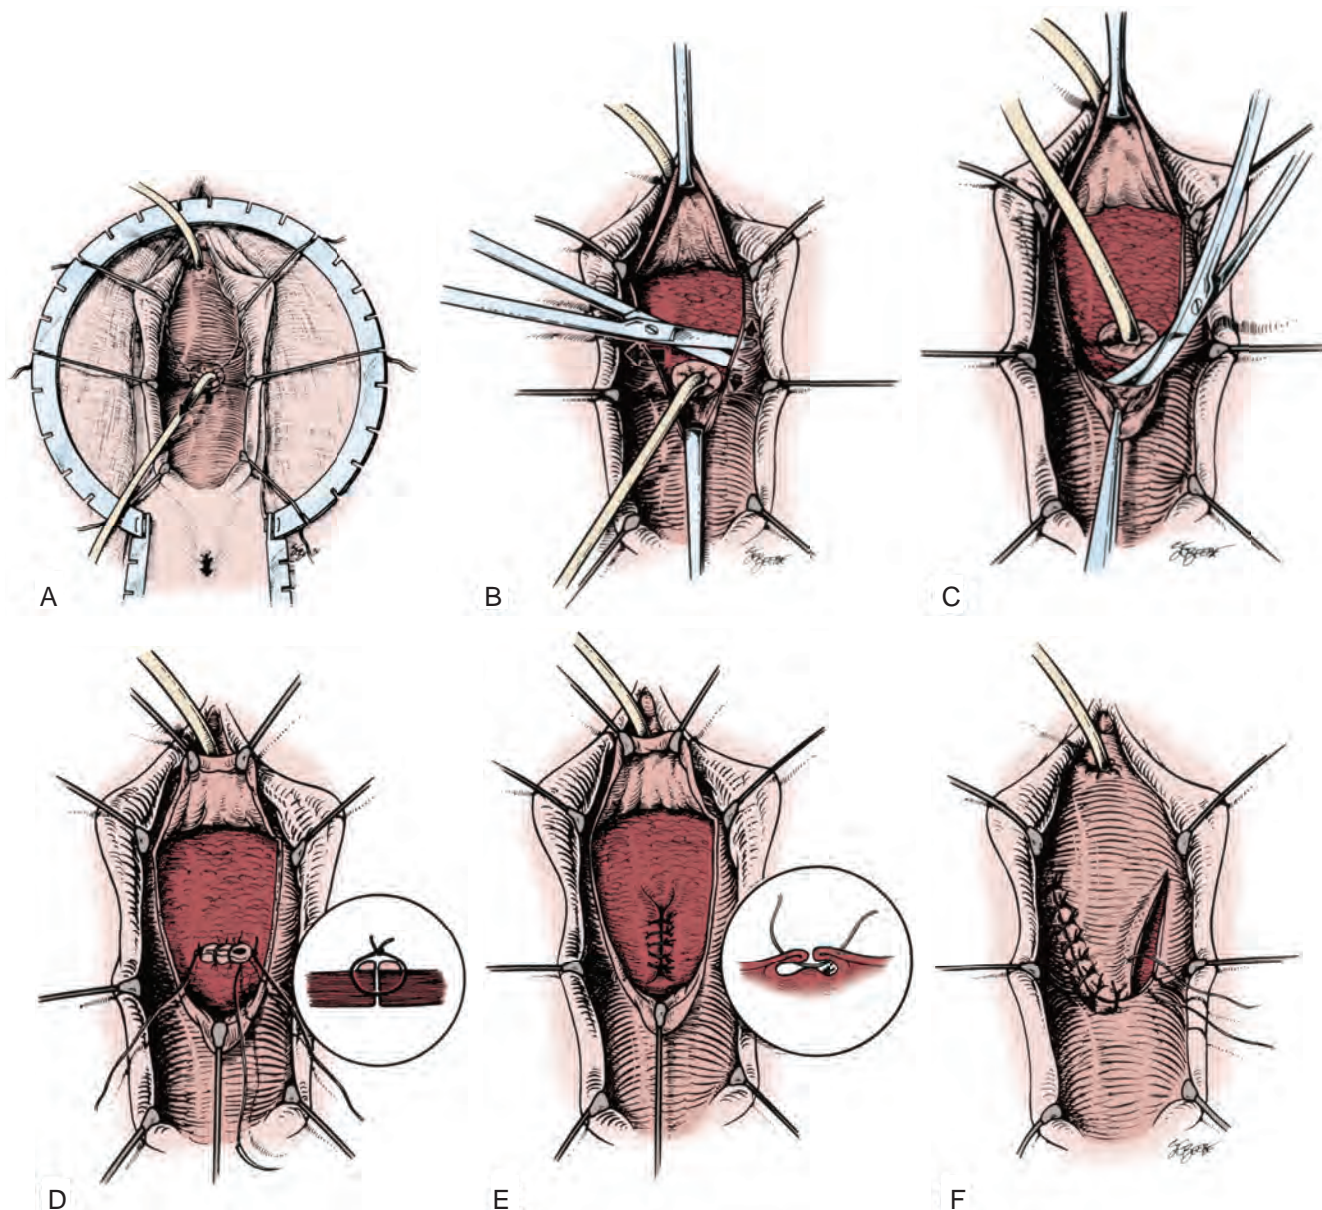

Figure 89-12. Technique of vaginal repair of a posthysterectomy vesicovaginal fistula (VVF). A, Retraction including ring retractor, vaginal speculum, and Foley catheter in the VVF tract. A Foley catheter is seen in the VVF tract providing traction on the vaginal cuff. B, Mobilization of anterior vaginal wall flap. Lateral flaps are developed as well, thereby isolating the VVF tract. C, Mobilization of posterior vaginal wall flap. D, Initial layer of closure is performed without excising the edges of the fistula tract. E, The perivesical fascia is closed with Lembert-type sutures. This line of closure is perpendicular to the initial suture line. F, The vaginal wall flaps are advanced to avoid overlapping suture lines. (From Ganabathi K, Sirls L, Zimmern P, et al. *Vesicovaginal fistulae: reconstructive techniques*. In: McAninch J, editor. *Traumatic and reconstructive urology*. Philadelphia: Saunders; 1996. p. 317.)

of the bladder. Large or small bowel may be used for augmentation cystoplasty, depending on the clinical circumstances.

Transvesical. A suprapubic transvesical approach to VVF repair has also been described (Landes, 1979; Cetin et al, 1988; Gil-Vernet et al, 1989). In this approach, the bladder is opened through a vertical cystotomy but is not bivalved down to the VVF tract. From a transvesical approach, the VVF tract is circumscribed and excised transvesically. The vaginal edges are then carefully mobilized from the bladder. The vagina and bladder are closed sequentially. A V-shaped flap of adjacent posterior bladder wall may be brought down as a flap to close a large gap or to minimize overlapping

suture lines (Gil-Vernet et al, 1989). This approach has been successful in both simple and complex fistula (Gil-Vernet et al, 1989; Leng et al, 1998), and modifications have been described incorporating an omental flap (Hellenthal et al, 2007).

Laparoscopic and Robotic Approaches. Laparoscopic VVF repair is an alternative to the classical open approach described previously. Compared with the O'Connor transabdominal approach, laparoscopic repair is reported to be associated with less surgical trauma, shorter convalescence, and lower morbidity (Nezhat et al, 1994; von Theobald et al, 1998; Miklos et al, 1999; Ou et al, 2004). Laparoscopic VVF repair is most useful in the same scenarios as the

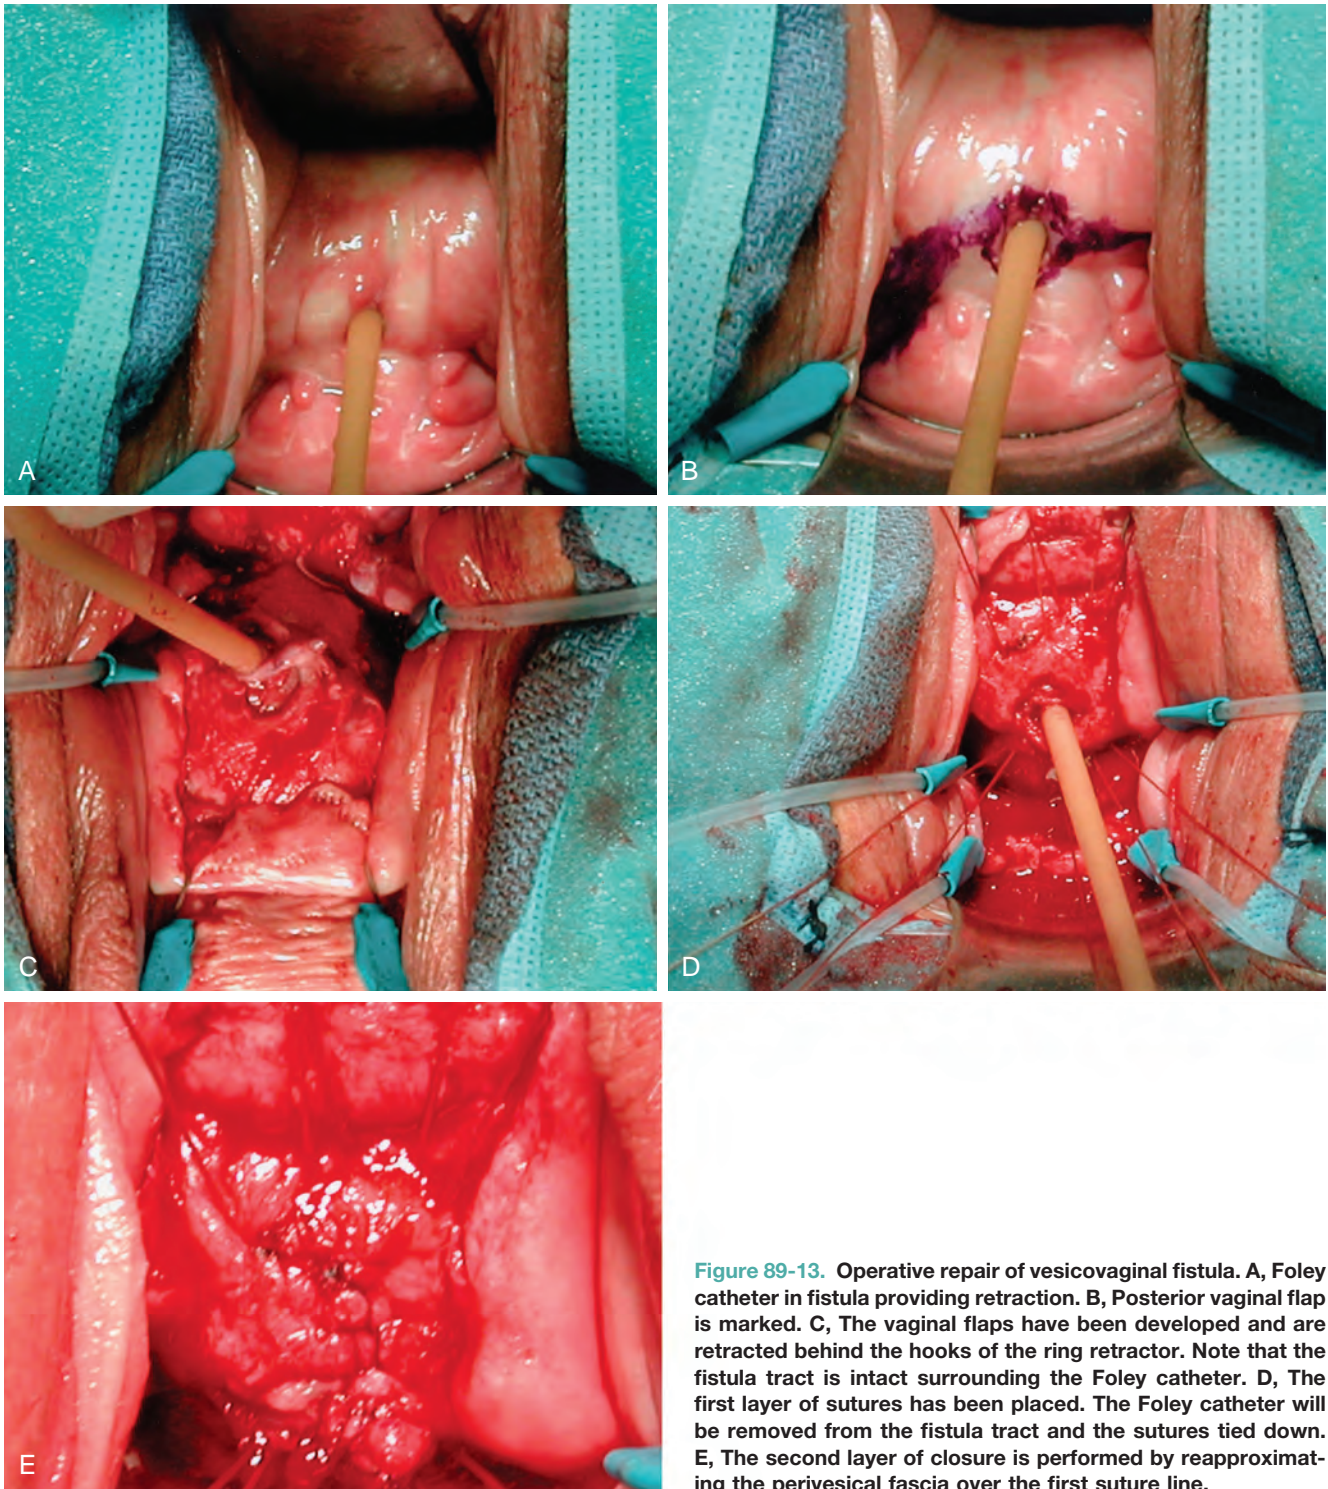

Figure 89-13. Operative repair of vesicovaginal fistula. A, Foley catheter in fistula providing retraction. B, Posterior vaginal flap is marked. C, The vaginal flaps have been developed and are retracted behind the hooks of the ring retractor. Note that the fistula tract is intact surrounding the Foley catheter. D, The first layer of sutures has been placed. The Foley catheter will be removed from the fistula tract and the sutures tied down. E, The second layer of closure is performed by reapproximating the perivesical fascia over the first suture line.

transabdominal repair, such as in the setting of a high VVF in which a vaginal operation would be anatomically challenging. Dense pelvic adhesions and/or inflammation from prior abdominal surgery can make this approach less desirable in some patients. Furthermore, intracorporeal laparoscopic suturing, a requirement for VVF repair, is an advanced skill many surgeons lack. Because of these limitations, the laparoscopic VVF repair has not been widely adopted.

Successful robotic VVF repair was first reported in 2005 (Melamud et al, 2005), and several small case series have been subsequently reported (Sundaram et al, 2006; Hemal et al, 2008). A five-port

technique has been described using a vaginal pack to maintain pneumoperitoneum throughout the case (Sundaram et al, 2006; Hemal et al, 2008). Removal of the vaginal packing without loss of pneumoperitoneum confirms successful closure. Advantages to the robotic technique include three-dimensional visualization, wristed instrumentation reducing the severe angulation required for laparoscopic VVF repair, and technically simpler intracorporeal knot tying.

Although there have been no direct comparisons among the classical transabdominal VVF repair, transvaginal VVF repair, and the minimally invasive robotic and laparoscopic techniques, it is

Figure 89-14. Intraoperative photograph from a suprapubic vesicovaginal fistula (VVF) repair. The bladder has been opened anteriorly and bivalved in the midline down to the level of a very large VVF. The gauze packing lies in the vagina. The ureteral catheters were placed to identify the ureters intraoperatively.

doubtful that a single procedure will emerge as the optimal surgery for all patients with VVF, given the variability in the nature of the condition, the patients in whom it occurs, and the expertise of individual surgeons.

Adjuvant Procedures in the Repair of Vesicovaginal Fistula: Tissue Interposition. The interposition of a healthy, well-vascularized tissue flap during VVF repair may be beneficial under certain circumstances. Tissue flaps are especially helpful in the setting of complex fistulae, such as those that have recurred after a prior attempt at repair, those related to previous radiotherapy, ischemic or obstetric fistulae, large fistulae, and, finally, those associated with a difficult or tenuous closure because of poor tissue quality. For VVFs repaired transvaginally, a labial fat pad (Martius flap) or a peritoneal flap is most commonly used. From a transabdominal approach, omentum or peritoneum is often used as an interpositional flap (Eisen et al, 1974).

Martius Flap. For low or distal fistulae, a Martius fibrofatty labial flap is a reliable source of tissue. The fibrofatty labial flap was first described by Heinrich Martius in 1928. This flap consists of adipose tissue and connective tissue and is the preferential tissue for fistulae involving the trigone, bladder neck, and urethra (Zimmern et al, 1986; Rangnekar et al, 2000). The blood supply

to the flap derives inferiorly from the posterior labial vessels (off the internal pudendal artery), superiorly from the external pudendal artery, and laterally from the obturator artery. The lateral blood supply is sacrificed during mobilization of the flap; the flap may be divided at either its most superior or inferior margin (basing the blood supply on the inferior or superior vascular pedicle, respectively), depending on where the flap will be transferred (Figs. 89-31 and 89-32).

Please see the Expert Consult website for further details.

Rangnekar and colleagues (2000) reported on the usefulness of the Martius flap in both urethrovaginal fistulae and VVFs, the majority of which (32 of 46) were a result of obstetric trauma. Of the VVF repairs, 4 of 21 repairs without a Martius flap failed, compared with none of the 13 procedures that included an adjuvant Martius flap. Eilber and colleagues (2003) reported that 33 of 34 (97%) patients undergoing repair of a distal VVF with a Martius flap were cured after the first operation.

For posthysterectomy fistulae, the distance from the labial harvesting site of the Martius flap to the fistula at the apex of the vagina may be considerable. Mobilizing and then tunneling the Martius flap to reach this location may compromise its blood supply and viability. In these cases, a peritoneal flap is preferred (Raz et al, 1993).

Peritoneal Flap. The use of a peritoneal flap during transvaginal repair of a complex VVF is a simple procedure that does not require extravaginal harvesting of the flap. This technique is primarily used in conjunction with repair of a high-lying posthysterectomy VVF (Raz et al, 1993; Eilber et al, 2003). Notably, peritoneal flaps may also be used as an adjunctive measure during transabdominal repair of VVF, although the approach and technique are vastly different (Eisen et al, 1974).

After a two-layer closure as described previously, the peritoneum is identified posteriorly. The peritoneum and preperitoneal fat are identified, isolated, and mobilized from the caudal origin of the vaginal wall flap using sharp dissection. Usually, dissection just beyond the posterior wall of the bladder will expose the edge of the peritoneum in the anterior cul-de-sac (Raz et al, 1993). The peritoneum is identified as a distinct layer from the bladder. The peritoneum is not opened but is mobilized and then advanced over the fistula repair and secured with interrupted absorbable sutures in a tension-free manner (Fig. 89-33). If a peritoneotomy is made during dissection or mobilization, the peritoneal defect can be closed as the flap is secured to the perivesical fascia over the fistula repair. The vaginal flap is then advanced and closed as previously described.

Raz initially reported success in 9 of 11 patients with high VVF undergoing peritoneal flap placement (Raz et al, 1993). A later study from the same institution reported on the use of peritoneal flaps in 83 patients, of whom 80 were cured after the first operation (Eilber et al, 2003). Two of the 3 patients with failed procedures underwent successful repair with a repeat transvaginal repair and peritoneal flap; the 1 remaining patient required a transabdominal repair with omental interposition.

Greater Omentum. The omentum is a particularly useful structure in the repair of VVF. Although most commonly used as an adjunct during transabdominal VVF repair (an interpositional layer between the bladder and vagina), it has occasional usefulness in transvaginal VVF repair, if it had been brought down into the pelvis during a prior surgical procedure. Favorable properties of the omentum include its ability to be mobilized on a well-vascularized pedicle into the deep pelvis without tension, its inherent lymphatic properties, its ability to contribute to healing even in the presence of infection, and the ease with which epithelialization occurs on its surface (Turner-Warwick, 1976; Wein et al, 1980b).

Please see the Expert Consult website for further details.

Evans and colleagues (2001) reported retrospectively on the use of an omental interpositional flap in 37 patients undergoing transabdominal VVF. Of the 29 patients with a benign cause of VVF, all 10 patients in whom an omental flap was used were cured, compared with only 12 of 19 (63%) in whom an omental flap was not used. Orford and Theron (1985) reported a 93% cure rate with the use of an omental pedicle graft in 52 patients undergoing VVF

See Table 89-2 and Box 89-5.

Step 1: Patient's Position, Bimanual Examination, and Cystoscopy. Under general anesthesia, the patient is placed in the lithotomy position, and a bimanual as well as a speculum examination is performed. Cystoscopy and insertion of ureteral catheters helps identify and protect the ureters during surgical dissection. When feasible, ureteral catheter of a different color or a Glidewire (Terumo Interventional Systems, Somerset, NJ) should be placed across the fistula emerging from the vagina. An indwelling urethral Foley catheter is placed. Gentle traction is applied on the Foley catheter to mechanically block the bladder neck and prevent CO₂ leakage. However, if this is not sufficient, a sponge is inserted into the vagina up to the vaginal apex to prevent CO₂ leakage.

Step 2: Port Placement. The pneumoperitoneum is established, and a three-port transabdominal approach is used. A primary 10-mm port is inserted in the midline supraumbilically. The laparoscope is introduced, and two 5-mm ports are placed lateral to the rectus muscle between ipsilateral spinoumbilical line. Additional ports are created in both iliac fossae under laparoscopic vision as per requirements and difficulty in surgery.

Step 3: Adhesiolysis and Dissection. Often, adhesions are present in these cases and require lysis from the posterior surface of the urinary bladder. Once this has been completed, dissection is started around the fistulous site. The peritoneum between the bladder and vagina is incised. The posterior bladder wall is incised vertically in the proximity of the fistula with cold scissors or an ultrasound scalpel, and dissection is continued until the catheter going across the fistula can be seen. The incision is carried downward as far as the fistula tract. This cystotomy requires wide dissection of the interveticovaginal plane so that the bladder can be easily separated from the vagina, to encircle the fistula. With use of laparoscopic scissors with gentle traction and countertraction, a plane is developed precisely between the bladder and vagina.

Step 4: Excision and Freshening Edges of the Fistula. The goal is to excise the fistulous tract all around until viable tissue margins in both the bladder and vagina are created. However, if this is difficult, then edges are freshened on either side of opening. The bladder wall is further separated from the vagina around the catheter to ensure adequate mobilization, and the vesicovaginal space is extended laterally to allow for tension-free suturing. Traction on the urethral catheter balloon helps facilitate sharp dissection of the plane between bladder and vagina. A sponge retractor in the vagina helps to elevate the vaginal fornices to guide the dissection.

Step 5: Reconstruction. Basic VVF repair is done in three layers. Vaginal closure is initiated at the apex of the incision with viable tissue in one layer using a continuous transverse 2-0 synthetic absorbable suture (Vicryl, Ethicon) or more recently barbed suture is commonly used for this step. Closure of the vagina is followed by interposition of the omentum or pericolic or mesenteric fat over the vaginal suture line. A suture is then placed at the anterior vaginal wall, distal to the vaginal closure. This suture is then used to anchor part of the omental flap, which can be harvested from the nearest anatomic location. Bladder closure is subsequently performed in two layers: first, mucosal closure with continuous 3-0 synthetic absorbable suture, then the seromuscular closure with interrupted 2-0 synthetic absorbable suture.

Step 6: Checking of Watertight Closure, Drain Placement, and Removal of Ureteric Catheters. The bladder is filled with 150 mL of water to assess the watertight closure. Bladder drainage is usually accomplished by a 20-Fr urethral Foley catheter. Usually a suprapubic cystostomy is not required. A drain is placed into the pelvic cavity. Bilateral ureteral catheters are removed sequentially if present.

Patient's Preparation. Mechanical and antibacterial bowel preparation the day before surgery is not done routinely except in cases of complicated VVF. A prophylactic dose of weight-adjusted low-molecular-weight heparin can be given the evening before surgery and every 24 hours thereafter until ambulation. Antibiotic is given within an hour of incision.

Patient's Position. General endotracheal anesthesia is administered.

During cystoscopy the patient is placed in lithotomy position with the operating table positioned horizontally, taking great care to facilitate the movement of the C-arm between the kidney and bladder area. This is for the placement of the ureteral catheters as well as a catheter through the fistula site if possible.

The patient in the dorsolithotomy position is secured to the table, with care taken to pad all pressure points, and her arms are tucked. Shoulder bolsters (TrenStop [Steris, Mentor, OH]) are applied to prevent cranial slide. Position is tested by placing the patient in steep Trendelenburg position. The patient is finally placed into a low lithotomy position to allow complete access to the vagina and bladder. A sterile field is created by preparing the perineum and proximal thighs and infraxiphoid abdomen using chlorhexidine gluconate after clipper shaving. A Foley catheter is placed per urethra to straight drain, and the ureteral catheters and catheter traversing through the fistulous opening are kept in the sterile area.

Finally, for commencement of the omentum mobilization for tissue interposition, the patient is placed back in an almost horizontal position, parallel with the floor (0 to 15 degrees), thus contributing to the performance of tension-free fixation of the omentum and helping to keep the small bowel contents in the epigastrium. In addition, the hips and the knees are only slightly flexed to reduce the distance between the mesentery root and os pubis, facilitating a tension-free approximation of omentum to the VVF area.

Port Placement (Fig. 89-16). Next, a high-flow, low-pressure pneumoperitoneum is obtained using a Veress technique in the supra-umbilical midline after the aspiration and drop test is passed. Next, a 12-mm camera port is placed 5 cm above the umbilicus. Inspection of the peritoneal cavity is performed to look for adhesions. Two additional ports are placed as follows: a left paramedian 8-mm robotic port, a left far lateral 8-mm robotic port, a right paramedian 8-mm robotic port, and a 5-mm port for suction and assistance or AirSeal system (SurgiQuest, Milford, CT). The robot is placed between the patient's legs and docked to the ports. Alternatively, side docking can be done, because this may allow more room for vaginal manipulation if needed.

Figure 89-16. Sites for port placement for robotic repair of vesicovaginal fistula. (Courtesy Dr. Ashok K. Hemal, Wake Forest University.)

Any da Vinci system can be used, but the new Si system with four arms is preferred. With use of the new system, the trocars can be placed relatively independent of the patient's body habitus and higher, which is very important in cases with difficult mobilization of the omentum.

Surgical Steps of Robotic-Assisted Laparoscopic Vesicovaginal Fistula Repair

Bimanual examination and cystoscopy. Bimanual examination and cystoscopy are performed as in the laparoscopic approach.

Adhesiolysis. In a patient with prior abdominal procedures, the first trocar can be inserted preferably using the Hasson technique. After inspection of the peritoneal cavity, a meticulous adhesiolysis of the omentum and bowel is performed from the surrounding structures, especially in the pouch of Douglas. With a combination of sharp and blunt dissection with plasma kinetic or Maryland fenestrated bipolar forceps and monopolar curved scissors, adhesiolysis is carried out to delineate the anterior surface of the uterus (if present) and the superior aspect of the bladder. The small bowel loops and/or the sigmoid colon usually requires careful dissection off the bladder in posthysterectomy patients. Trendelenburg tilt allows the intestinal contents to fall cranially. Sometimes release of the adhesions close to the port sites is necessary laparoscopically before placement of all ports for the robotic device.

Techniques of localization and exposure of fistula. The bladder is identified by moving or traction on the Foley catheter. There are three ways to approach the fistula to avoid O'Connor's technique of bivalving the bladder.

1. Posterior cystotomy. (Figs. 89-17 to 89-25 illustrate posterior cystotomy technique for robotic repair of VVF.) In direct proximity and superior to the VVF, the posterior bladder wall is incised vertically with the monopolar robotic scissors. The cystotomy is continued in the direction of the catheter that defines the fistula, completely opening the posterior bladder wall and encircling the fistulous opening. If the fistulous tract is relatively small and visible through the cystotomy, the vaginally placed ureteral catheter, which was used as a marker for the fistula, is cut and removed.
2. Vaginal incision with cystotomy. In this approach the incision can be made from the normal part of vagina starting on the anterior surface. The incision is carried vertically downward, encircling the fistula. The ureteric or Foley catheter that runs along the fistulous tract is manipulated by the bedside assistant and identified from the movement of bladder wall, which allows the creation of minimal cystotomy.

Figure 89-27. Dissected bladder (arrow) and vaginal (arrowhead) site of fistula with a catheter across. (Courtesy Dr. Ashok K. Hemal, Wake Forest University.)

3. Minimal dissection technique. (Figs. 89-26 to 89-30 illustrate the minimal dissection technique for robotic repair of VVF in a different case.) Under three-dimensional stereoscopic vision, a gentle drawing on the ureteral catheter, which was passed through the VVF, is usually helpful for the location of the approximate site of the fistula. The dissection is commenced in this area, and once the area has been identified by manipulation of the catheter, then a small cystotomy is created to identify the catheter across the fistula. Subsequently the incision is extended on either side as per requirement.

Excision of fistulous tract and refreshing of edges of fistula on bladder and vaginal site. The margins of resection of the fistulous tract are further dissected using monopolar robotic scissors. If the fistula is large and/or not completely identified, then the vaginally placed Foley catheter is pulled intra-abdominally through the cystotomy and is used as a retractor for the anterior bladder wall to splint open the cystotomy, thus allowing better visualization of the fistula and the stented ureteric orifices. There is no need to excise the borders of the fistulous tract widely as long as a lateral margin of viable tissue is visible. This is another advantage of magnification available with a minimally invasive approach. Occasionally, a wide excision may be necessary to expose the communication between the bladder and vagina. The excised tissue is sent for histologic examination.

Mobilization of the bladder and vaginal flap for tension-free reconstruction. The bladder and vaginal flaps are created to provide tension-free closure using cold scissors and with sparing use of plasmakinetic forceps for hemostasis if there is bleeding. Use of a fourth arm helps in providing traction and countertraction. Once the bladder wall is fully mobilized off the anterior aspect of the vagina, the preplaced ureteral catheters are helpful in identifying the ureteric orifices and preventing inadvertent injury to the ureters. Further mobilization and separation of the posterior wall of the bladder from the anterior vaginal wall allows a tension-free closure. Because the trigone and ureteric orifices invariably lie in close proximity to the fistulous edges, it is important to avoid uncontrolled blunt and wide excision, which may hamper subsequent closure. It is preferable to do a slow and careful sharp dissection of the fistulous edges, which must be freshened.

Figure 89-30. Omentum is tacked over vaginal repair (arrow); repaired bladder in two layers (arrowhead). (Courtesy Dr. Ashok K. Hemal, Wake Forest University.)

Figure 89-29. Reconstruction of vagina in two layers (arrowhead); bladder wall repaired in two layers (arrow). (Courtesy Dr. Ashok K. Hemal, Wake Forest University.)

Reconstruction of vagina and bladder. The closure of vagina is performed using 3-0 barbed suture, which is placed transversely for tension-free closure as a running watertight suture. If the size and the orientation of the vaginal gap allow less tension on the closure line, a vertically placed suture line could be acceptable.

Reconstruction of the bladder. The bladder is usually closed in a vertical manner to minimize the contact surface of suture lines. However, it depends on the size of the fistula. Also, after dissection, sometimes these can have a dog ear-shaped deformity. Bladder closure is initiated at the caudal part or close to the trigone area or at the most distal part of cystotomy near the ureteric orifices. If single-layer closure is performed, then 3-0 barbed suture is a good choice. If two-layer closure is contemplated, then the first layer includes mucosa and a portion of detrusor muscle layer using a 4-0 monofilament absorbable suture in a running continuous fashion. The second layer of detrusor muscle is then done. If the cystotomy is quite long, the bladder closure can be started from the proximal

open bladder edge until the superoposterior part of the bladder is closed. Then, with new suture, the most distal segment of the cystotomy is closed until the two are securely knotted together approximately in the middle of the cystotomy line. In so doing, the proximal suture can be used as traction to provide better exposure and subsequently improved visualization for the critical part of the cystotomy closure near the ureteric orifices. In addition, using two separate sutures for cystotomy closure avoids possible laxity of the single suture line. Second-layer bladder closure can be performed using 3-0 barbed suture. Watertight closure is confirmed by filling the bladder with 150 mL of water.

Interposition of the tissue. Tissue interposition between the bladder and vaginal suture lines is performed, preferably using a well-vascularized pedicle of omentum. To reduce tension on the vascular pedicle of omentum and better mobilize this in the lower abdomen, the patient is placed in an almost horizontal position. In case the omentum is completely retracted in the upper abdomen, it can be mobilized in the beginning and can be tagged to pelvis. Whenever omentum is easily available, it is the best choice and should always be used for interposition between the suture lines. If omentum is unavailable or cannot be adequately mobilized, the epiploic appendices of the sigmoid colon or a peritoneal flap from the nearest anatomic location is used as tissue for interposition.

Fixation of interpositional tissue. At the anterior vaginal wall distal to the vaginal closure, a 3-0 barbed suture is placed, which is used as a fixation to anchor the interpositional tissue. To avoid any contact between both suture lines and provide stability on fixation, the interpositional tissue is anchored with a suture on the resilient vaginal wall and distally to the end of the vaginal closure line. To prevent laxity on fixation, the interpositional tissue is also fixed left and right on the peritoneal edges of the cystotomy. Thus the interpositional tissue completely covers the suture line of the vagina, forming a triangle; each point is fixed on elastic and well-vascularized tissue.

Catheter and drain. A 20-Fr indwelling catheter is placed. No suprapubic cystostomy tube is placed. A 15-Fr Jackson-Pratt is introduced into the pelvis through left robotic port and secured to the skin with a silk suture.

Exiting cannula and closure. Reducing the pressure of pneumoperitoneum under 10 mm Hg, the robotic and assistant trocar sites are removed under endoscopic guidance to make sure there is no bleeding from vessels of the abdominal wall. At the end, the fascia of the 12-mm camera port is closed with monofilament absorbable suture. The skin is closed with 4-0 Monocryl subcuticular sutures.

Postoperative care after robotic VVF repair is different from that of the open procedure and may include the following.

1. The drain is typically removed within 24 hours postoperatively or when drainage fluid is less than 50 mL. Typically patients go home within 24 to 48 hours with an indwelling urethral catheter, which ensures continuous drainage of the bladder and proper healing. Typically, suprapubic cystostomy tube is not placed. If required, anticholinergics are used to prevent bladder spasms.
2. Normally the urethral catheter is removed on postoperative day 7 to 14, depending on the quality of reconstruction and the surgeon's preference. A retrograde cystogram may be performed before removal of the bladder catheter to confirm fistula closure but is not always mandatory. Patients are warned to avoid the use of tampons and refrain from sexual activity for at least 8 weeks postoperatively.
3. Appropriate prophylactic antibiotics are generally given as per protocol. The patient typically starts antibiotics a day before catheter removal.
4. Early mobilization and ambulation are encouraged using the principles of fast-track postoperative care: no nasogastric tube, with mobilization starting 6 hours after the end of the procedure. The patient is started on a liquid diet same evening and is progressed to a normal diet the next day.

Robotic-assisted laparoscopic repair has led to higher success rates over pure laparoscopy, which is technically more difficult. Conversion to open surgery may be required based on nonprogression of surgery, severe inflammation, severe adhesions, or difficulty in suturing or if there is a requirement for simultaneous bladder augmentation.

Major complications have been reported, including compartment syndrome in lower extremities, enterocutaneous fistula, and inferior epigastric artery injury, with the overall major complication rate being 2.3%.

Laparoscopic Repair of Vesicovaginal Fistula. The first laparoscopic repair of VVF was reported by [Nezhat and colleagues \(1994\)](#). Later [Nabi and Hemal \(2001\)](#) reported a modified technique of laparoscopic repair of VVF and right nephrectomy for a nonfunctioning kidney in a single session. Sotelo and colleagues reported an expeditious approach, intentionally opening first the bladder, leading accurately to the fistulous tract without the need for additional vaginal incisions or further dissection of the vesicovaginal space. Several series involving laparoscopic repair of VVF have been reported. Important series have been summarized in [Table 89-3](#). The operation time varies from 70 minutes to 390 minutes in different studies. Hospital stay depends on the practice policies in different countries. A few studies reported that patients were discharged with a urethral catheter and drain on the first postoperative day, whereas other centers kept their patients in the hospital while the urethral catheter and drain were kept in place for up to 2 weeks. In the available data the recurrence rate of the fistula is about 6.5% and the overall success rate is about 93.5%. Laparoscopy allows fistula repair with a limited bladder incision, unlike in an open procedure, with all the advantages of minimally invasive procedures such as a magnified view of the operative field, hemostasis, decreased hospital stay, and shorter convalescence.

Robotic-Assisted Laparoscopic Repair of Vesicovaginal Fistula. See [Table 89-4](#).

The first case series of robotic-assisted laparoscopic repair of VVF with step-by-step technique was reported by Hemal and associates in 2006 ([Sundaram et al, 2006](#)). This series included six patients with advantages of shorter hospital stay, faster recovery, and less morbidity. Later, other authors reported their experience with use of robotic assistance.

Hemal and colleagues also reported the first series of complex VVF robotic repairs, reporting their experience in seven cases of recurrent supratrigonal fistulae in which they first intentionally incised the bladder ([Gupta et al, 2010](#)).

The success rate reported for robotic-assisted repair was close to 100% in most of these small series, with the potential advantage that the robotic device allows more surgeons to use this minimally invasive approach.

Laparoscopic versus Robotic versus Open Approach. There is no level 1 evidence to prove superiority of one approach over another. Outcomes depend on the surgeon's experience and practice. Minimally invasive series demonstrate efficacy in primary VVF repair with acceptable success rates. Two retrospective studies described transition from open to laparoscopic repair and found that the latter was minimally invasive with similar success ([Ou et al, 2004](#)). In another retrospective case-matched study of 32 patients, Gupta and colleagues evaluated robotic-assisted laparoscopic versus open repair for recurrent VVF without any significant statistical difference in success rate (100% vs. 90%), mean operative time, complication rate, use of interpositional flap (omental vs. peritoneum), or complications (0% vs. 10%). The most significant difference between the two groups was shorter average hospitalization (3.1 vs. 5 days) favoring the robotic-assisted group, with decreased morbidity as opposed to open surgery ([Gupta et al, 2010](#)).

The key points of surgery include vaginoscopy and cystoscopy to assess the fistula and placement of ureteral catheters through the fistula and normal ureters. One of the important steps to be considered is the transvaginal catheterization of the VVF. This is achieved by placement of a ureteral catheter from the bladder, cystoscopically, cannulating the fistula and retrieving it from the vagina. Occasionally a reverse “railroading” is needed owing to the angulation of the fistulous tract, wherein the guidewire is placed transvaginally and retrieved from the bladder transurethrally. If the fistula is large, a Foley catheter can be directly placed transvaginally into the bladder. Tugging the catheter aids in locating the approximate site of the fistula as seen from within the abdominal cavity, allowing the placement of a minimal cystotomy near the area of interest, close to the midline. However, a Foley catheter placed transvaginally through the fistula into the bladder allows better appreciation of the movement and location in the transperitoneal endoscopic view.

Steps to avoid complications. Ureteral catheterization is an important step to prevent inadvertent ureteral injury during dissection as well as during reconstruction. It allows visualization of the ureteric orifices within the bladder, preventing the surgeon from taking a stitch too close to them during bladder reconstruction. It also keeps the operating field relatively dry, and ureteral catheters can be removed at the end of the procedure.

Adequate adhesiolysis is mandatory before a vesicotomy is performed. The primary causative procedure will invariably lead to intraperitoneal adhesion. Such adhesions could be parietal in nature, wherein adhesiolysis may be necessary to allow appropriate port placement, or could be visceral wherein bowel loops may obscure the area of interest in the pelvis. Gentle and sharp dissection to aid the bowel to fall away is imperative to prevent a bowel injury during fistula dissection and to allow tension-free closure of the vagina and bladder.

The modified technique prevents bivalving of the bladder and extensive dissection. Posterior cystotomy or limited dissection to quickly access the fistulous site and subsequent meticulous dissection and freshening of edges or, if needed, excision of fibrous edge are necessary. “Stay midline” is probably the safest dictum to prevent ureteral injury during dissection.

It is important to mobilize well-vascularized flaps to allow tension-free closure. An interposing tissue is useful for the success of repair.

If available, omentum is preferred, especially when repairing recurrent fistula, because it helps in rapid absorption of the inflammatory exudates owing to abundant lymph supply, and it significantly decreases the chance of failure.

The optimal approach for VVF repair depends on surgeon expertise. Transvaginal repair remains a minimally invasive approach with little morbidity and convalescence in the hands of a skilled and experienced surgeon. For patients requiring an open abdominal approach or flap interposition, laparoscopic or robotic-assisted approaches offer decreased morbidity and convalescence compared with traditional open techniques. The surgeon's experience and skill set guide the selection of surgical approach, taking into account the cause, localization, size, time of presentation, and complexity of the fistula. If available, use of robotic assistance in laparoscopy is the preferred approach for minimally invasive surgeons.

The flap is harvested after the first two layers of closure of the VVF but before advancing the final vaginal wall flap over the repair (see earlier discussion). To harvest the flap, a vertical incision is made over the labia majora. The borders of dissection include the labio-crural fold laterally, the labia minora and the bulbocavernosus muscle medially, and Colles fascia covering the urogenital diaphragm posteriorly. Flap harvest is accomplished in a lateral to medial fashion. Dissecting down to the adductor muscles laterally before coming around the width of the Martius flap facilitates the harvest of a thick, fatty segment for flap placement. Before final division of the flap inferiorly or superiorly, mobilization may be facilitated by gentle downward traction using a Penrose drain, incorporating the entire thickness of the fibrofatty flap. For a posterior-based flap, the main vascular supply to the flap is located at the base of the labia majora. The anterior segment is clamped and transected anterior to the pubic symphysis (see [Fig. 89-31](#)).

With the flap having been mobilized, a tunnel is created from the labial incision to the site of the fistula repair (see [Fig. 89-32](#)). A hemostat is used to transfer the fibrofatty flap from the harvest site, through the tunnel, to the level of the fistula repair. The flap is placed over the fistula repair and secured with interrupted absorbable sutures in a tension-free manner. The vaginal wall flap is advanced over the Martius flap and closed as previously described. A small Jackson-Pratt or Penrose drain may be left in the labial incision in the operative bed. The labial incision is closed, and a pressure dressing may be applied to the labial skin incision.

The blood supply of the greater omentum derives principally from the right and left gastroepiploic arteries, as well as the distal branches of the gastroduodenal and splenic arteries, respectively. The right and left gastroepiploic arteries join along the greater curvature of the stomach to form the gastroepiploic arch. The arterial anatomy within the greater omentum is variable but usually consists of a right and left omental artery, and occasionally a middle omental artery, all of which run perpendicular to their origin off the gastroepiploic arch. The caliber of the right gastroepiploic artery is usually larger than the left one, which generally favors a pedicle based on this artery; however, in practice, a pedicle based on either artery may be used (Kiricuta and Goldstein, 1972; Bissada and Bissada, 1992). In addition, anatomically, the origin of the right gastroepiploic artery is somewhat caudal compared with the left one, allowing a slight advantage in reaching into the deep pelvis. In some cases, the free distal end of the greater omentum is long enough to reach into the deep pelvis in a tension-free manner without any further mobilization. In either situation, the omental flap is secured with absorbable suture to healthy tissue at a location distal to and beyond the closed VVF tract, between the vagina and bladder. Securing the omental flap beyond and between the suture lines of the closed viscera prevents overlying or apposed suture lines.

Figure 89-15. Diagrams of suprapubic repair of vesicovaginal fistula (VVF). A, The bladder opened and bivalved down to the level of the VVF. B, The VVF tract is excised. C, After closure of the vagina, the bladder is closed in multiple layers. D, Omentum is interposed between the bladder and vaginal closures. (From Ganabathi K, Sirls L, Zimmer P, et al. Vesicovaginal fistulae: reconstructive techniques. In: McAninch J, editor. *Traumatic and reconstructive urology*. Philadelphia: Saunders; 1996. p. 315.)

repair. In addition to its use in routine posthysterectomy VVF, the omentum is reported to be a useful adjunct in complicated or complex cases, such as those associated with large VVFs (Kiricuta and Goldstein, 1972; Bissada and McDonald, 1983), obstetric VVFs (Baines et al, 1976; Sharma et al, 1980), and VVFs associated with radiation therapy (Bissada and Bissada, 1992; Evans et al, 2001).

Other Flap and Graft Techniques. A variety of flaps including gracilis muscle flaps (Izes et al, 1992), labial myocutaneous flaps (Symmonds and Hill, 1978), seromuscular intestinal flaps (Mraz and Sutory, 1994), and rectus abdominis flaps (Menchaca et al, 1990; Viennas et al, 1995; Reynolds et al, 2008) have been used as adjunctive measures in the repair of complex VVF. Obstetric fistulae associated with significant urethral loss may be repaired, in part, with the use of anterior or posterior bladder flaps (Hanash and Sieck, 1983; Elkins et al, 1992; Khanna, 1992). The gracilis muscle in the medial thigh is a convenient adjunct to repair large soft-tissue defects, especially those associated with radiation therapy (Obrink and Bunne, 1978; Heckler, 1980). The gracilis muscle is in close proximity to the vagina and has a reliable blood supply. The muscle is mobilized through a thigh incision from its distal attachment on the tibial condyle, with care taken to preserve its blood supply. It is

tunneled cephalad into the vagina subcutaneously and secured over the fistula. Bilateral gracilis muscle flaps can be used for total vaginal reconstruction.

Bladder mucosa as a free graft has been used for repair of VVF (Brandt et al, 1998; Ostad et al, 1998; Sharifi-Aghdas et al, 2002). The bladder is approached extraperitoneally and a small cystotomy is performed. The fistula tract is identified and denuded of mucosa circumferentially for approximately 1 cm. A free graft of bladder mucosa is harvested from the edge of the cystotomy and placed over the denuded VVF tract and secured in place with absorbable suture. Brandt and colleagues (1998) reported a 96.3% success rate in 80 patients. Ostad and colleagues (1998) reported on 6 patients with complex, high, irradiated, large or recurrent VVF, all of whom were cured by this technique.

Outcomes of Vesicovaginal Fistula Repair. The success rate reported for a simple VVF repair in the modern era, whether through an abdominal or vaginal approach, is in excess of 90% (Table 89-5 on the Expert Consult website). Long-term follow-up suggests that the majority of patients are greatly improved, although minimally bothersome symptoms may persist in a minority of patients over the long term, causing little impact on quality of life (Dolan et al,

2008). Complicated VVFs, including those resulting from obstetric causes (Elkins et al, 1988; Arrowsmith, 1994), larger fistulae, and those associated with radiation therapy, generally have lower success rates (Massee et al, 1964; Hedlund and Lindstedt, 1987; Langkilde et al, 1999; Ockrim et al, 2009). Massee and colleagues (1964) reported a 93.8% cure rate of urinary vaginal fistulae resulting from surgical trauma, but only a 66.7% cure rate for those caused by radiation therapy. Some authors have suggested that urinary diversion should be strongly considered as primary therapy (Murray et al, 2002) for radiation-induced fistulae because the results with surgical repair in this group are less than optimal (Langkilde et al, 1999). In patients with obstetric fistulae associated with loss of the bladder neck and proximal urethra, relatively high rates of persistent severe sphincteric incontinence are noted despite successful repair of the VVF (Murray et al, 2002; Browning, 2004), and this type of fistula is involved in the majority of treatment failures (Kelly, 1992). Thus despite a technically successful VVF

Figure 89-33. Peritoneal flap. A, Diagrammatic representation of the location of the peritoneal flap during vesicovaginal fistula repair. B, Diagram of peritoneal flap advanced over fistula repair. (A and B, From Raz S. Fistulae: transvaginal repair of vesicovaginal and urethrovaginal fistulae. In: Raz S, editor. Atlas of transvaginal surgery. 2nd ed. Philadelphia: Saunders; 2002. p. 242.)

repair, functionally, from the patient's perspective, some of these individuals may not be significantly improved after the repair owing to severe stress urinary incontinence (SUI). Pubovaginal slings and periurethral injectable agents are often beneficial in these patients, once the VVF has been surgically closed (Arrowsmith, 1994). In the developing world, access to synthetic mid-urethral slings is limited. Furthermore, the safety of using such materials in the setting of extensive reconstruction, such as that after repair of an obstetric fistula, is not established.

Vesicovaginal Fistula and Urinary Diversion. In some patients, repair of VVF is not possible or multiple surgical attempts have failed. This is probably most commonly associated with existing pelvic malignancy, severe radiation damage, and/or large soft-tissue loss, especially in the setting of obstetric fistula. However, some patients may simply not be candidates for repair owing to coexistent medical morbidities, making them a prohibitive surgical risk. In the former group, urinary diversion in the form of either a urinary conduit (Kisner and Kesner, 1987) or a continent reservoir can be considered. Fistulae in patients who are not candidates for surgical intervention may be managed by percutaneous ureteral occlusion and permanent nephrostomy (Kinn et al, 1986; Stern et al, 1987; Hubner et al, 1992; Farrell et al, 1997; Amsellem-Ouazana et al, 2006; Natarajan et al, 2007; Shindel et al, 2007).

In the developing world, where catheters and ostomy appliances are either too expensive or completely unavailable, continent urinary diversion or incontinent urostomies are often not practical, which presents ethical issues with the alternative treatments (Wall et al, 2008). In these situations, internal urinary diversion with ureterosigmoidostomy has some application in patients with unreconstructable lower urinary tracts (Attah and Ozumba, 1993). It should be recognized that this is clearly a last-resort operation owing to its significant metabolic and neoplastic potential.

KEY POINTS: VESICOVAGINAL FISTULAE

- VVF is the most common acquired fistula of the urinary tract.
- In the industrialized world, surgical injury to the bladder is the most common cause of VVF, most commonly seen after hysterectomy. In the developing world, VVF is most commonly related to complications from obstructed labor.
- VVFs caused by radiation therapy are usually complex.
- VVF occurring in the setting of a history of pelvic malignancy should undergo biopsy before repair to exclude recurrent malignancy as a cause of the fistula.
- Diagnosis of VVF can be confirmed on VCUG. Voiding images should be obtained if the fistula was not demonstrated on the filling images of the cystogram.
- Upper tract imaging is obtained after a diagnosis of VVF to exclude injury to the ureter(s).
- Small, oblique fistulae may respond to conservative therapy, including prolonged urinary catheterization with or without fulguration of the fistula tract.
- There is no optimal method for the surgical repair of all VVFs. In the properly selected patient, transabdominal and transvaginal approaches to fistula repair have similar success rates. Laparoscopic and robotic approaches for VVF repair are advancing the field. Adjuvant tissue flaps may be useful to prevent surgical failure in the setting of complex or recurrent fistula, radiation fistula, obstetric fistula, and fistulae with tenuous repairs.

Ureterovaginal Fistula

Ureteral fistulae to the genital tract in the female most often connect with the vagina but have also been reported to connect with other

genital structures, including the fallopian tube (Crochet et al, 2008) or uterus (Billmeyer et al, 2001). Risk factors for the development of ureterovaginal fistulae include endometriosis, obesity, pelvic inflammatory disease (Symmonds, 1976), and radiation therapy and pelvic malignancy. Nevertheless, Symmonds has noted that the patient with a ureteral injury after gynecologic surgery is typically one who had an uncomplicated, technically easy hysterectomy for minimal disease (Symmonds, 1976). Thus, except for those oncologic cases wherein a segment of ureter is deliberately excised, many ureteral injuries are likely the result of technical or iatrogenic factors.

Etiology and Presentation

The most common cause of ureterovaginal fistulae is surgical injury to the distal ureter, with gynecologic procedures being by far the most common (Symmonds, 1976; Dowling et al, 1986; Badenoch et al, 1987; Lee et al, 1988; Blandy et al, 1991) (Box 89-6). The incidence of iatrogenic ureteral injury during major gynecologic surgery is estimated to be about 0.5% to 2.5% (Symmonds, 1976; Payne, 1996; Gilmour et al, 1999). A large prospective case series from Finland found an incidence of ureteral injury associated with hysterectomy for benign pathology of 0.2% (10 of 5279), with the lowest rate associated with vaginal hysterectomy and no difference between open and laparoscopic abdominal hysterectomy (Brunner et al, 2011). The incidences of immediate and delayed ureteral injury during radical hysterectomy were found to be 1.3% (7 of 536) and 2.4% (13 of 536), respectively, in a series from Serbia; injuries appeared more common after prolonged surgery and in patients with diabetes, obesity, or wound infection (Likic et al, 2008). A registry study from the United States found an overall incidence of ureteral injury during radical hysterectomy of 0.8% (Frankman, 2010). Case series from referral centers in India, Pakistan, and Egypt showed that the proportion of urinary tract injuries resulting from obstetric or gynecologic surgical trauma that primarily affected the ureter varied from 1% to 23% (Kumar et al, 2009; Sachdev et al, 2009; Nawaz et al, 2010; El-Tabey et al, 2011).

The mechanism of injury resulting in iatrogenic postoperative ureterovaginal fistulae includes ureteral laceration or transection, blunt avulsion, crush injury, partial or complete suture ligation, and, finally, ischemia caused by operative devitalization of the ureteral vascular supply and/or cautery injury. Overall, the ureter is most commonly injured during gynecologic surgery in the distal one third or pelvic portion, which is, accordingly, the only location at which a ureteral injury may result in a

ureterovaginal fistula. Not uncommonly this occurs inadvertently during an attempt by the surgeon to control active bleeding using clamps or suture ligation of large tissue segments in the deep pelvis.

The pelvic ureter is intimately related to the female genital tract throughout its course. **In the deep pelvis, the ureter passes at the lateral edge of the uterosacral ligament and ventral to the uterine artery, and then passes just lateral to the cervix and fornix of the vagina.** In close apposition to these structures, the ureter must be carefully avoided during any gynecologic procedure in the deep pelvis. **Any injury to the ureter that exposes the ureteral lumen (i.e., laceration) or results in delayed necrosis of a portion of the ureter (i.e., suture ligation) and subsequent urinary extravasation may lead to a fistula.** A ureterovaginal fistula may result from a sequence of events, including urinary extravasation from the ureteral injury, urinoma formation, subsequent extension along non-anatomic planes created during surgery, and eventual drainage through the vaginal incision or an ischemic area of the vaginal cuff. Infection, prior radiation therapy, or other factors that may impede healing probably promote the development of ureterovaginal fistulae under these circumstances.

The most common presenting symptom is the onset of constant urinary incontinence 1 to 4 weeks after surgery (Mandal et al, 1990). This may have been preceded by several days of flank or abdominal pain, nausea, and low-grade fever, presumably as a result of urinoma and/or obstruction of the kidney (Lee et al, 1988). Flank pain will often be masked in the postoperative period because of the use of postoperative narcotic analgesics. **Of importance, and in direct contrast to VVF, in the setting of continuous urine leakage from a ureterovaginal fistula, patients will continue to report normal voiding habits because bladder filling is maintained from the contralateral, presumably undamaged, upper urinary tract.**

Prevention

Ureterovaginal fistula occurring in the early postoperative phase predominantly after hysterectomy is the most frequent presentation to urologists of upper urinary tract fistula. A randomized study involving 3141 women undergoing open or laparoscopic gynecologic surgery lasting for longer than 30 minutes found that the

incidence of ureteral injury after prophylactic insertion of ureteral stents (1.2% [19 of 1583]) was similar to controls (1.1% [17 of 1558]) (Chou et al, 2009). A previous cost analysis from the U.S. perspective suggested that stenting was worthwhile only if the risk of injury was higher than 3.2% (Schimpf et al, 2008). If injury does occur, many cases, even those involving bilateral injury, can be managed by endoscopic techniques (Shaw et al, 2008).

Diagnosis and Management

Unfortunately, intraoperative diagnosis of a genitourinary (GU) or GI injury is made in only about half of the cases that result in fistula (Ostrzenski and Ostrzenska, 1998). In one study, 36% of VVFs were found within 1 week of a laparoscopic hysterectomy and 50% in the second week. Most patients who had undergone transabdominal hysterectomies had leakage in the second week (90%) (Kochakarn and Pummangura, 2007).

Diagnosis and confirmation of a ureterovaginal fistula can usually be accomplished with a combination of a relevant history, physical examination, and appropriate radiologic studies, including cross-sectional imaging (such as a CT urogram), IVU, and retrograde pyelography (Mandal et al, 1990) (Fig. 89-34). Urine may extravasate externally or internally. Creatinine levels in the urine are higher than serum levels. Therefore, in the setting of a suspected fistula, testing the creatinine level in either the extravasated fluid or the accumulated ascites and comparing this value to the the serum creatinine levels will confirm urinary leakage but not the location of the fistula. Likewise, testing potassium levels will show higher levels compared with serum levels (Kruger and Whiteside, 2003).

A double dye test may be of some value in differentiating between a ureterovaginal fistula and VVF as a cause of ongoing urinary leakage (Raghavaiah, 1974). Suspicion of a ureterovaginal fistula should prompt upper tract imaging (Badenoch et al, 1987). The IVU or CT urogram most commonly will demonstrate some degree of ureteral obstruction and associated caliectasis or ureteral dilation (Selzman et al, 1995). These findings in the presence of constant vaginal drainage strongly suggest a ureterovaginal fistula. Alternatively, if the fistula is mature and large, the upper urinary tract may appear completely unremarkable; however, urine will be seen opacifying the vagina before the postvoid image

Figure 89-34. Diagnosis of ureterovaginal fistula. A, Normal cystogram in a woman with constant urinary drainage after undergoing an abdominal hysterectomy. B, Retrograde pyelogram demonstrates a distal ureteral stricture with a small fistula tract (white arrow) with contrast in the vagina (black arrows) superimposed on contrast in the bladder from the contralateral retrograde ureterogram.

Figure 89-35. Ureterovaginal fistula. A, Oblique view on intravenous urography shows mild left-sided hydroureteronephrosis associated with a distal tapering of the ureter. B, Faint and subtle opacification of the vagina (white arrows) is somewhat obscured by bladder filling (bladder edge indicated by black arrows) on this oblique image. C, Lateral view demonstrates the ureter clearly entering the vagina. D, Retrograde pyelogram demonstrates abrupt termination of the distal ureter.

(Fig. 89-35). Antegrade pyelography after nephrostomy tube decompression of a partially obstructed ureter may be associated with similar findings (Fig. 89-36). A high oblique or lateral film may be necessary to differentiate the contrast in the bladder from that in the vagina. A retrograde pyelogram may show the ureter and fistula well or may demonstrate an abrupt termination of the ureter 2 to 4 cm from the ureteric orifice. If retrograde pyelography demonstrates the fistula, as well as ureteral continuity, then an attempt at stenting is warranted. Cystography is performed primarily to exclude a coexistent VVF. A cystogram will not demonstrate the ureterovaginal fistula unless there is preexisting vesicoureteral reflux. Ureterovaginal fistulae may be seen on CT urography or MRI (Fig. 89-37); however, an additional role for such

cross-sectional imaging is to evaluate for an associated pelvic abscess or undrained urinoma. An unstructured review by Narayanan and colleagues suggested that MRI, particularly with T2 weighting, provided optimal diagnostic information regarding fistula associated with pelvic malignancy, with contrast-enhanced CT with late excretory phase an acceptable alternative (Narayanan et al, 2009). These newer modalities were considered to be superior to other x-ray contrast techniques and ultrasonography. MRI is also used more widely (Abou-El-Ghar et al, 2012).

The goal of therapy is the expeditious resolution of urinary leakage, avoidance of urosepsis, and preservation of renal function. Once the diagnosis is made, prompt drainage of the affected upper urinary tract is essential (Gerber and Schoenberg, 1993),

because partial ureteral obstruction is often present. An attempt at ureteral stenting or percutaneous nephrostomy tube decompression is warranted as soon as possible (Dowling et al, 1986; Kostakopoulos et al, 1998) if direct open surgical repair is not immediately considered. Occasionally, conservative, nonoperative management alone will result in fistula closure in patients with ureteral continuity and a normal-appearing ureter beyond the fistula (Alonso et al, 1986), although this is unusual. Endoscopic management, including ureteral stenting, may be sufficient to promote closure of the fistula in some cases. Dowling and colleagues (1986) reported that 11 of 23 patients with ureteral injuries recognized postoperatively

Figure 89-36. Ureterovaginal fistula. Antegrade nephrostogram demonstrates mild ureterectasis with opacification of the vagina (arrow).

were successfully managed with nephrostomy tube drainage and/or ureteral stenting. Selzman and coworkers (1995) reported successful management of 7 of 20 ureterovaginal fistulae with internal ureteral stenting alone. None of the 7 patients in whom a ureteral stent was successfully placed required open surgery. In general, if ureteral continuity can be demonstrated on imaging, retrograde placement of a stent is often possible. In some cases, an antegrade stent placement will be successful where a retrograde attempt had failed. The use of ureteral stenting in patients with ureterovaginal fistulae was reported in 11 studies, including 126 patients in total (Andriole et al, 1984; Lang, 1984; Dowling et al, 1986; Mandal et al, 1990; Barton et al, 1992; Koonings et al, 1992; Campbell et al, 1993; Lingeman et al, 1995; Beaghtler et al, 1997; Narang et al, 2007; Ustunsoz et al, 2008); this resulted in closure in 63 cases altogether. Success rates were 6% to 100%, although the overall closure rate across all series is calculated at $50\% \pm 18\%$.

If ureteral stenting is unsuccessful owing to complete ureteral occlusion or if prolonged leakage persists despite stenting, then formal surgical repair is indicated (Fig. 89-38). Timing of the repair of ureterovaginal fistulae is controversial. Some authors advocate early repair (Talbert et al, 1965; Flynn et al, 1979; Badenoch et al, 1987; Blandy et al, 1991; Selzman et al, 1995), whereas others recommend a delay of 4 to 8 weeks (Hulse et al, 1968; Lee and Symmonds, 1971). More recent literature suggests that early repair is preferred and is not associated with an increase in morbidity or higher failure rates (Payne, 1996).

As noted previously, ureterovaginal fistulae most commonly result from injury to the distal one third of the ureter below the level of the iliac vessels. The usual site of the injury is in the very distal ureter and the surrounding fibrosis and inflammation usually preclude primary repair of the fistula. Therefore open surgical repair most commonly involves ureteroneocystostomy. The ureter is located and dissected as distally as possible in the pelvis. Care is taken to preserve the periureteral adventitial layer to prevent ureteral ischemia. The ureter is divided distally, and a ureteroneocystostomy is performed with or without a psoas hitch. It is not important to create a tunneled anastomosis. Occasionally a Boari flap or replacement with bowel segments (with or without reconfiguration) may be necessary because of extensive ureteral injury. Robotic and laparoscopic repairs using the same principles as open repair have been reported (Modi et al, 2005; Laungani et al, 2008; Modi et al, 2008; Patil et al, 2008), with the potential benefits of shorter hospitalization and quicker convalescence. Recent case series suggest that this standard surgery can be performed safely and with reasonable operative times using laparoscopic or robotic techniques if

Figure 89-37. Computed tomography (CT) scan of ureterovaginal fistula. A, CT scan demonstrates contrast material within the bladder (B) and vagina (v). The ureter is visible (arrow) adjacent to the vagina. B, This image shows the ureter (arrow) entering the vagina.

surgeons with the relevant skills and appropriate facilities are available (Puntambekar et al, 2006; Laungani et al, 2008; Modi et al, 2008). A case report has suggested that open repair through the vagina is possible if abdominal access is problematic (Chen et al, 2007). Rarely, transureteroureterostomy, ileal substitution of the ureter, or renal autotransplantation is required. In patients with a normal contralateral kidney in whom there is extensive renal damage because of obstruction or infection, nephrectomy may be the most expeditious method of management.

Successful repair of ureterovaginal fistulae is expected in more than 90% of cases. Blandy and colleagues reported on early repair of iatrogenic injury to the ureter in 43 cases including 30 ureterovaginal fistulae. All patients were cured using a combination of techniques including the Boari flap (Blandy et al, 1991). Others have reported similar results (Lee and Symmonds, 1971; Flynn et al, 1979; Mandal et al, 1990).

Ureteral fistulae to other gynecologic organs have been reported. Ureterouterine fistulae may occur as a result of cesarean section, uterine malignancy, and elective abortion (Keegan and Forkowitz, 1982; Lazarevski and Badiev, 1996; Wang and Hung, 1997; Sheen et al, 1998). Uretero-fallopian tube fistulae have also been reported as a consequence of laparoscopic fulguration of endometriosis (Steckel et al, 1993).

KEY POINTS: URETEROVAGINAL FISTULAE

- Ureterovaginal fistulae occur more commonly after benign hysterectomy than after radical hysterectomy.
- Patients have constant urinary leakage but usually a normal voiding pattern.
- In the setting of ureteral patency, a trial of an indwelling ureteral stent may result in resolution of the fistula.
- If conservative management fails or if there is complete obstruction of the distal ureter, then ureteral reimplantation with or without a psoas hitch is usually curative.

Vesicouterine Fistula

Etiology and Presentation

Vesicouterine fistulae are among the least common urogynecologic fistulae. Less than 100 cases were reported in the world literature from 1908 to 1986, with no series having more than 4 patients

(Tancer, 1986). However, the incidence of this condition is increasing in parallel with the rising numbers of low-segment cesarean sections being done worldwide (Porcaro et al, 2002). Cesarean section is by far the most common cause of this unusual fistula (Tancer, 1986; Miklos et al, 1995; Vu et al, 1995). Tancer related that of the 74 cases of vesicouterine fistulae reported from 1947 to 1986, 57 followed low-segment cesarean section, 7 followed vaginal operative delivery, and the remaining cases were related to a variety of disparate scenarios, including induced abortion, hysterectomy, and dilation and curettage (D&C) (Tancer, 1986). Jozwik and colleagues (1997) reported that 21 of 24 vesicouterine fistulae treated over a 12-year period occurred after cesarean section, the majority of which were repeat cesarean sections. Those undergoing vaginal birth after prior cesarean section (VBAC) are also at risk for vesicouterine fistula (Gil and Sultana, 2001). Vesicouterine fistulae may occur spontaneously as a result of a ruptured uterus during obstructed labor. In these cases, the posterior bladder wall may tear along the uterine rupture line creating the potential for a fistula. Bladder wall invasion by chorionic villi penetrating beyond the uterine serosa, placenta percreta, may also create a vesicouterine fistula (Krysiewicz et al, 1988). A foreign body such as an intrauterine device (IUD) (Schwartzwald et al, 1986), uterine artery embolization (Sultana et al, 2002), brachytherapy (Memon et al, 1998), and traumatic bladder catheterization (Futter and Baker, 1995) have all been reported to cause vesicouterine fistula. In most cases, simultaneous injury to the bladder and uterus is the inciting event. An unrecognized and unrepaired (occult) bladder injury, or incorporation of a portion of the bladder during closure of the uterus during any number of operations, may result in a vesicouterine fistula. Anatomically, the most common location of the fistula is along the posterior bladder wall in the midline, or from the genital side, just cephalad to the internal cervical os.

Unlike other types of urogynecologic fistulae, vesicouterine fistulae may or may not manifest with constant urinary incontinence because of the sphincter-like activity of the cervix; the exception is in the setting of an incompetent cervix wherein urinary leakage is constant. In this clinical setting, which typically occurs after vaginal delivery, urine flows from the bladder through the fistula into the uterine cavity and then into the vagina through an incompetent cervical os. Tancer (1986) described 12 such patients, with urinary incontinence as the presenting symptom, out of 15 patients with vesicouterine fistulae after vaginal operative delivery. However, in the setting of a relevant clinical history, vesicouterine fistulae will also manifest with menouria and cyclic hematuria in the setting of urinary continence. Youssef syndrome describes the presenting symptom complex of vesicouterine fistula: menouria, cyclic hematuria with associated apparent amenorrhea, infertility, and urinary continence (Youssef, 1957; Tancer, 1986) in a patient who has undergone prior low-segment cesarean section. Endometriosis of the bladder, in which cyclic hematuria may be present, must be differentiated from this condition.

Diagnosis and Management

Diagnosis of vesicouterine fistula can be made by a combination of cystoscopy and radiographic studies, although a high degree of suspicion is necessary to pursue the diagnosis if initial radiographic studies prove negative (Smayra et al, 2005). Cystoscopy may demonstrate a midline lesion along the posterior bladder wall (Fig. 89-39). Urine cytology may reveal endothelial cells. Instillation of contrast material into the bladder (cystogram) will outline the uterine cavity (Fig. 89-40), whereas a hysterosalpingogram will demonstrate filling of the bladder. MRI, CT (Fig. 89-41), and ultrasonography have been used in the diagnosis and evaluation of vesicouterine fistulae as well (Mercader et al, 1995; Huang et al, 1996; Murphy et al, 1999). IVU or contrast-enhanced CT can be used to exclude concomitant ureteral injury.

Several different approaches have been advocated for the treatment of vesicouterine fistulae. Spontaneous resolution may occur, and Graziotti and colleagues (1978) noted that only five such cases,

including theirs, had previously been reported in the literature. Therefore these authors recommend against a “precocious” surgical repair of these lesions because time may allow some fistulae to resolve without surgery. Prolonged indwelling bladder catheterization or fulguration of the fistula tract followed by bladder drainage may be successful in select cases, especially in patients with small, immature fistulae (Graziotti et al, 1978; Molina et al, 1989; Ravi et al, 2003; Novi et al, 2004). Hormonal induction of menopause will induce involution of the puerperal uterus, and this principle has been used with some success in treating this condition as well (Hemal et al, 1994; Jozwik and Jozwik, 1999; Ravi et al, 2003). Jozwik and Jozwik (1999) reported successful treatment in eight of nine patients with use of hormonal manipulation.

Surgical therapy for vesicouterine fistulae is often contingent on the specific reproductive wishes of the patient (Smayra et al, 2005), as well as other surgical factors, but is considered definitive

therapy (DiMarco et al, 2006; Rao et al, 2006). If there is no further desire for childbearing, then transabdominal hysterectomy and bladder closure should be considered. Ureteral stents can be placed to facilitate identification of the ureters intraoperatively. After performance of the hysterectomy, the fistula tract on the posterior bladder wall is excised and the bladder is closed primarily. An omental flap can be placed into the deep pelvis to buttress the bladder closure and separate the bladder closure from the vaginal closure to reduce the possibility of a postoperative VVF. For the patient who desires preservation of fertility, uterine-sparing surgery can be considered. In a manner similar to an O’Conor transabdominal VVF repair, the bladder is opened and bivalved down to the fistula tract. Careful dissection allows separation of the bladder from the uterus beyond the fistula tract. The fistula tract is excised from both structures, the uterus and bladder are closed individually, and an interpositional flap, usually omentum, is secured between the two organs. Fertility is possible after repair of vesicouterine fistula. Lotocki and colleagues (1996) reported five pregnancies with four full-term deliveries in a cohort of 16 patients who had undergone uterine-sparing surgery for vesicouterine fistulae. Minimally invasive laparoscopic and robotic surgical approaches to the repair of vesicouterine fistulae have been reported (Miklos, 1999; Tarhan et al, 2007; Ramalingam et al, 2008).

Figure 89-39. Cystoscopic view of vesicouterine fistula before repair.

KEY POINTS: VESICOUTERINE FISTULAE

- The most common cause of vesicouterine fistulae is low-segment caesarean section.
- Vesicouterine fistulae do not always manifest with urinary incontinence.
- Nonsurgical management of vesicouterine fistulae is possible by hormonally inducing involution of the uterus with maintenance of urinary drainage.
- Management of vesicouterine fistulae is contingent on the reproductive wishes of the patient. Hysterectomy followed by repair of the bladder is indicated for the individual who no longer desires fertility. Uterine-sparing procedures can be used, and successful pregnancy is possible after vesicouterine fistula repair.

Figure 89-40. Cystogram demonstrating vesicouterine fistula in a postpartum woman. A, Filling of the bladder demonstrates a small amount of contrast material cephalad to the tip of the Foley catheter. The uterine cavity is faintly seen. B, Postvoid image demonstrates filling of the uterine cavity and cervical canal. The bladder is not well demonstrated. This patient's status is immediately postpartum. Contrast material in the vagina outlines the incompetent cervical canal and os.

Urethrovaginal Fistula

Etiology and Presentation

In the developing world, urethrovaginal fistula may occur as a result of obstructed labor with or without associated VVF. In industrialized countries, urethrovaginal fistulae in adults mostly have an iatrogenic cause.

In feminizing genital reconstructions in children with ambiguous genitalia and surgical repairs of cloacal malformations, urethrovaginal fistulae can occur as early or late complications (Dhabalia et al, 2009; Oguzkurt et al, 2009; Levitt and Pena, 2010; Levitt et al, 2011; Park et al, 2011). Also in transsexual adults undergoing female-to-male reconstruction, urethrovaginal fistulae have been reported (Hage et al, 1993).

In the surgical treatment of stress incontinence in women with bulking agents (Carlin and Klutke, 2000; Hilton, 2009) or synthetic slings, several cases of urethrovaginal fistula have been reported (Glavind and Larsen, 2001; Reisenauer et al, 2007; Morton and

Hilton, 2009; Estevez et al, 2010). Even conservative treatment of prolapse with pessaries can lead to the formation of fistula if these pessaries are neglected for an extended period of time, although fistula formation after only 2 weeks of pessary use has been described (Walker et al, 2011; Hilton and Cromwell, 2012).

Trauma—including inappropriate catheterization—and foreign bodies are obvious causes of fistula (Parkhurst et al, 1981; Holland et al, 2001; Blaivas and Purohit, 2008; Liu et al, 2008; Cameron and Atiemo, 2009; Kobayashi et al, 2010; Thrumurthy et al, 2010).

Urethral diverticula and their surgical repair may also lead to urethrovaginal fistula (Ganabathi et al, 1994; Ben Amna et al, 2002; Porgiglia et al, 2002).

Urethrovaginal fistula has also been described in some Behçet patients with vasculitis and local necrosis of the urethrovaginal septum (Waidelich et al, 1994; Chung et al, 2005).

Complications of radiation therapy for pelvic malignancy can also result in the formation of urethrovaginal fistula (Flottorp and Inversen, 1960) (Figs. 89-42 and 89-43). Other causes of urethrovaginal fistulae include trauma (including pelvic fracture) and vaginal neoplasms. Another important cause in the long-term-care setting is urethral catheter erosion (Trop and Bennett, 1992; Andrews and Shah, 1998). In patients with poor sensation, especially the cognitively or otherwise neurologically impaired patient, pressure necrosis from a chronically indwelling catheter may result in traumatic hypospadias and urethrovaginal fistula. If the condition is not recognized, over time the catheter may erode to the level of the bladder neck and beyond, effectively creating a bivalved urethra and a urethrovesicovaginal fistula (Fig. 89-44).

Symptoms of urethrovaginal fistulae are largely dependent on the size and location of the fistula along the urethral lumen. A small fistula may produce only minimal leakage, whereas a large urethrovaginal fistula can cause continuous urine drainage. Proximal fistulae can be associated with stress incontinence, or, if they are located at the bladder neck, continuous incontinence may result, similar to that associated with VVF. Distal fistulae beyond the sphincteric mechanism may be completely asymptomatic or may be associated with a splayed urinary stream. Occasionally, distal fistulae are associated with vaginal voiding and pseudoincontinence, so called because the patient reports urinary incontinence that occurs only when rising from a seated position after voiding. This occurs as a result of urine accumulation in the vagina during voiding, with emptying occurring on standing—so-called vaginal voiding (Fig. 89-45).

Figure 89-41. Computed tomography scan with contrast enhancement demonstrating a vesicouterine fistula. Contrast material is layering in the partially filled urinary bladder; contrast opacification of the uterine canal (arrow) suggests a vesicouterine fistula.

Figure 89-42. Urethrovaginal fistula after mid-urethral synthetic sling procedure. A, Intraoperative view demonstrating a urethrovaginal fistula at the bladder neck after a mid-urethral sling procedure. B, Cystoscopy demonstrates intraurethral sling material with calcified material.

Figure 89-43. Urethrovaginal fistula at the bladder neck from obstructed labor. A hemostat is shown entering the urethral meatus. (Courtesy Mark Morgan, MD, Department of Obstetrics and Gynecology, Hospital of the University of Pennsylvania, Philadelphia, PA.)

Figure 89-44. Severe complete erosion of the urethra secondary to chronic indwelling urinary catheter. This patient with advanced multiple sclerosis underwent surgical bladder neck closure and ileovesicostomy (ileal chimney). B, bladder; v, vagina.

Diagnosis and Management

The diagnosis of urethrovaginal fistula can often be made on physical examination and cystourethroscopy; however, voiding cystourethrography is most useful (Fig. 89-46), especially in complex cases. Small fistulae may be very difficult to locate on

Figure 89-45. Urethrovaginal fistula on lateral voiding image from voiding cystourethrography demonstrates fistula (black arrow) in this patient with a primary symptom of vaginal voiding. The urethra proximal and distal to the fistula is well opacified (white arrows). B, bladder; V, vagina.

Figure 89-46. This patient was referred for the evaluation of persistent incontinence after urethral diverticulectomy. A voiding cystourethrogram demonstrates incomplete resection of the urethral diverticulum (white arrow) with a pinpoint postoperative urethrovaginal fistula (black arrow shows a small amount of contrast material faintly outlining the anterior vaginal wall). Resection of the residual diverticulum with repair of the fistula by a Martius flap was curative.

physical examination, even with a speculum, owing to the surrounding vaginal rugation (Fig. 89-47). It is important to note that an associated VVF will be found in up to 20% of cases, and therefore a thorough evaluation of the entire lower urinary tract is warranted (Lee et al, 1988).

Figure 89-47. Urethrovaginal fistula. Identification of the exact fistula tract can be difficult in redo cases. Passage of a flexible wire endoscopically from the urethral lumen into the vagina can aid in locating the fistula tract.

Figure 89-48. Endoscopic view of a urethrovaginal fistula (arrow). This patient reported ongoing urinary incontinence for 10 years after an endoscopic bladder neck suspension. BN, bladder neck.

Endoscopic examination of the urethra should be performed. However, because of its short length, the female urethra may be difficult to fully examine with a standard rigid cystoscope, because the irrigation fluid is discharged 1 to 2 cm proximal to the lens. A flexible cystoscope or a specially designed female cystoscope with a short beak is very helpful in visualizing the entire urethral lumen, because the irrigation fluid is discharged next to the lens, distending the adjacent urethral lumen (Fig. 89-48). Once the diagnosis is

made on cystoscopy, the bladder is examined for additional fistulae. Video-urodynamics may accurately characterize any associated incontinence, including that associated with detrusor dysfunction, although this will not often influence the decision of closing the fistula. This study also allows assessment of the anatomic relationship of the fistula to the bladder neck and urethra, as well as examination for associated VVF.

The surgical repair of urethrovaginal fistulae is challenging and can often be more difficult than repair of VVF. This is a result of several factors, including extensive soft-tissue defects as well as the lack of local viable tissue for a multilayer repair (Keettel et al, 1978). Repair of urethrovaginal fistulae usually involves the use of rotational vaginal wall flaps, but anterior-based (Elkins et al, 1992) and posterior-based (Khanna, 1992) bladder flap tubes have been used as well.

A number of factors should be considered before repair. If the fistula is the result of a foreign body, such as a synthetic sling (Reisenauer et al, 2007), the foreign material should be excised as widely as possible from the margins of the fistula, debridement performed on the associated devitalized or inflamed tissue, and then the fistula closed with healthy tissues and flaps, if necessary. Small fistulae may be managed by a multilayered closure, usually with an interpositional graft such as a Martius flap (Webster et al, 1984; Leach, 1991). Larger fistulae, including those resulting from obstructed labor, may require extensive surgery, including urethral reconstruction (Tehan et al, 1980; Elkins et al, 1992; Wang and Hadley, 1993). Distal fistulae without associated voiding symptoms or incontinence may be observed or, alternatively, can be managed with an extended meatotomy (Lamensdorf et al, 1977). The quality of the vaginal tissues should be optimized before operative repair, which may include the use of antibiotics to treat associated infection, or topical estrogen treatment in patients with significant atrophic vaginitis. Similar to VVF, timing of repair is controversial. Some authors have suggested that a waiting time of 2 to 6 months is advisable in most patients, with a waiting period of up to 1 year in those with radiation fistulae (Webster et al, 1984; Zimmern et al, 1986). Other authors have advocated immediate repair as soon as the vaginal tissues are free of infection and inflammation (Blaivas, 1989; Blaivas et al, 1995).

Operative Technique. The repair of urethrovaginal fistulae is conceptually very similar to the vaginal flap repair of VVF described previously. The patient is positioned in the dorsal lithotomy position, and urethral and suprapubic catheters are placed. A ring retractor is helpful for exposure. Allis clamps are used to reflect the vaginal wall cephalad, exposing the fistula. In some patients an episiotomy may facilitate exposure of the fistula, improving visualization for repair (Webster et al, 1984). However, because of the distal (with respect to the vagina) location of these lesions, this is not usually necessary.

After infiltration of the fistula margins with injectable saline, the fistula tract is circumscribed through the vaginal wall (Fig. 89-49). The fistula tract and immediate surrounding epithelium are not typically excised, because this will create a larger defect in the urethra that will be more difficult to close without undue tension. However, the vaginal wall is dissected several millimeters from the edge of the circumscribed fistula tract in a radial orientation. An inverted U- or J-shaped incision is marked along the anterior vaginal wall, with the base of the U or J at the margin of the circumscribed fistula tract. This is infiltrated with injectable saline, and the anterior vaginal wall flap is developed, exposing the underlying periurethral fascia to the level of the bladder neck or beyond, depending on the size and location of the fistula. If a concomitant anti-incontinence procedure is planned, dissection may be carried out laterally from the edges of the flap at the level of the bladder neck and the retropubic space entered.

The edges of the circumscribed tract are reflected over the fistula and apposed with absorbable suture to create the first layer of closure. The periurethral fascia is then reapproximated in a perpendicular suture to the first layer of closure, thereby minimizing overlap. At this point, a Martius flap or other adjuvant flap can be secured over the periurethral fascia. Finally, the anterior vaginal wall

Figure 89-49. Operative diagram of urethrovaginal fistula repair. A, Inverted U incision is made in the anterior vaginal wall with the base of the U at the proximal margin of the fistula. The fistula is circumscribed. B, The anterior vaginal wall flap is mobilized, exposing the periurethral fascia. Dissection is also carried out laterally and distally from the margins of the fistula. The edges of the fistula tract are not excised. C, The epithelialized margins of the fistula tract are reapproximated with absorbable suture for the initial layer of closure. The periurethral fascia may be closed as a second layer, imbricating the initial layer of closure (not shown). D, A Martius flap may be harvested from the labia majora and tunneled as an additional layer of closure. E, The anterior vaginal wall flap is advanced over the closure and secured with absorbable suture. (From Leach GE, Kobashi KC. Urethral diverticulum and fistula. In: Cardozo L, Staskin D, editors. Textbook of female urology and urogynecology. London: Isis Medical Media; 2001. p. 721–45.)

flap is brought over the repair, including a Martius flap if used, and secured beyond the original fistula tract.

Adjuvant Flaps and Procedures in the Repair of Urethrovaginal Fistula. Various types of soft-tissue flaps are often an important component of a successful urethrovaginal fistula repair

because fistula excision and vaginal flap advancement have been historically associated with a high rate of failure (Birkhoff et al, 1977; Keettel et al, 1978; Davis et al, 1980; Patil et al, 1980; Leach, 1991; Fall, 1995; Bruce et al, 2000; Rangnekar et al, 2000). A variety of adjuvant procedures have been used in the repair of

urethrovaginal fistulae, including, most commonly, a Martius labial fat flap, but also gracilis and rectus abdominis muscle, myocutaneous flaps, vaginal wall flaps, fibrin glue, and free labial skin grafts (Keettel et al, 1978; McKinney, 1979; Tolle et al, 1981; Webster et al, 1984; Krogh et al, 1989; Leach, 1991; Izes et al, 1992; Candi-ani et al, 1993; Fall, 1995; Rangnekar et al, 2000). Whereas in obstetric fistula repair it was not found to have any benefit in a large retrospective study in 440 women, the labial bulbocavernosus muscle and fat flap by Martius is still considered by some to be an important adjunctive measure in the treatment of GU fistula wherein additional bulking with well-vascularized tissue is needed (Browning, 2006). Rangnekar and colleagues reported on 12 patients with urethrovaginal fistula, of whom 8 were treated with a Martius flap and 4 with a conventional repair. Only 1 of the 8 had a fistula recurrence, whereas 3 of the 4 conventional repairs broke down; it should be noted, however, that these cases were not randomized between surgical techniques (Rangnekar et al, 2000). Puneekar and colleagues described 15 patients with complex and recurrent fistula; these authors used the skin island flap modification with excellent results (Puneekar et al, 1999). Radopoulos published the findings of a small series of 5 recurrent and complex urethrovaginal fistulae that all healed with use of a Martius flap (Radopoulos et al, 2008). The series involving fistulae of nonobstetric causes are small, and all of them are retrospective. There are no prospective data, nor randomized studies (Birkhoff et al, 1977; Baskin et al, 2005). The indications for Martius flap in the repair of all types of fistula remain unclear.

Webster and colleagues (1984) reported on 11 patients with urethrovaginal fistulae, of whom 10 underwent surgical repair. Three of the 10 had recurrence of the fistula, all of whom were salvaged with a subsequent repair combined with a Martius labial fat pad interposition. Two patients had primary repair with a Martius flap (see prior discussion under VVF for a more complete discussion of the Martius flap), and both were cured. These authors recommended a Martius flap for all patients undergoing urethrovaginal fistula repair. Bruce and colleagues (2000) reported on the use of a pedicled rectus abdominis muscle flap based on the inferior epigastric artery for complex and refractory urethrovaginal fistulae in 6 patients. In all patients, at least one attempt at repair with a Martius flap had failed. Six of 6 patients remained successfully closed at a mean follow-up of 23 months. One of 6 patients had persistent urge incontinence postoperatively. The authors concluded that the rectus abdominis flap is a useful adjunct in the repair of complex or refractory urethrovaginal fistulae.

Suprapubic as opposed to urethral catheterization postoperatively for at least 14 days to allow adequate healing has been suggested (Tehan et al, 1980; Webster et al, 1984), although the use of only a single drainage catheter postoperatively is not universally agreed on. Other authors use both a suprapubic and a urethral catheter (Leach, 1991). Anticholinergics are administered liberally to reduce bladder irritability. Usually a VCUG with contrast administered through the suprapubic tube is obtained to document resolution of the fistula.

SUI may persist after repair of urethrovaginal fistulae. Whether repair of SUI should be done concomitantly with the fistula surgery or should be deferred until after repair of the fistula is controversial. Blaivas and colleagues (1989) argued that sphincteric incontinence should be repaired at the time of fistula surgery, with a Martius flap interposed between the fistula repair and a pubovaginal fascial sling. Webster and colleagues (1984) suggested that SUI associated with a proximal or mid-urethral urethrovaginal fistula should not be corrected until the fistula is closed and the patient reassessed for persistent incontinence. These authors suggest, however, that SUI associated with distal urethrovaginal fistula can be repaired concomitantly.

Overall, the success rate of urethrovaginal fistula repair is variable but is not generally considered to be as high as that for VVF repair (Gerber and Schoenberg, 1993). Not uncommonly, two or more procedures may be necessary to achieve a satisfactory result (Webster et al, 1984).

KEY POINTS: URETHROVAGINAL FISTULAE

- Distal urethrovaginal fistulae are often asymptomatic, whereas proximal fistulae may cause intermittent or constant urinary leakage.
- Urethrovaginal fistulae caused by surgical trauma may be difficult to visualize on physical examination or cystoscopy.
- Diagnosis of a urethrovaginal fistula is best made with VCUG.
- Repair of urethrovaginal fistulae can be challenging and often involves an interpositional tissue flap because of the relative lack of surrounding connective tissue in the mid-urethra and distal urethra.

UROENTERIC FISTULAE

Vesicoenteric Fistula

Etiology and Presentation

Vesicoenteric fistulae commonly occur in the setting of bowel disease, such as diverticulitis, colorectal carcinoma, and Crohn disease. Less common causes include radiation, infection, and trauma—external penetrating trauma, as well as iatrogenic surgical trauma. Diverticulitis is the most common cause of colovesical fistulae in most series, accounting for approximately 70% of cases (Mileski et al, 1987; Pollard et al, 1987; Walker et al, 2002; Najjar et al, 2004) (Table 89-6). The second most common cause of vesicoenteric fistulae is cancer, followed by Crohn disease. The peak incidence of vesicoenteric fistula occurs at 55 to 65 years of age, although fistulae from Crohn disease manifest much earlier (Badlani et al, 1980). Approximately 2% of patients with diverticulitis may experience a colovesical fistula as a complication of their disease (Hafner et al, 1962). In a multi-institutional retrospective review of 400 patients with Crohn disease over a 10-year period, 8 patients (2%) were found to have enterovesical fistulae (Gruner et al, 2002). The underlying GI tract disease strongly influences the type of fistula; ileovesical fistulae are more common in Crohn disease than in cancer, and colovesical fistulae are usually a result of diverticulitis.

Symptoms of vesicoenteric fistulae may originate from the urinary or GI tract; however, in general, lower urinary tract symptoms are more common at presentation (Morse and Dretler, 1974; Ray et al, 1976). In the early stages, symptoms are nonspecific and relate to lower urinary tract dysfunction. Lower urinary tract symptoms include pneumaturia, frequency, urgency, suprapubic pain, recurrent urinary tract infections (UTIs), and hematuria (Table 89-7). Pneumaturia is considered the most common presenting symptom noted in 50% to 70% of cases (Morse and Dretler, 1974; Pontari et al, 1992; Jarrett and Vaughan, 1995; Solem et al, 2002). GI symptoms may include fecaluria and tenesmus. The classic presentation of vesicoenteric fistula is described as Gouverneur syndrome and consists of suprapubic pain, urinary frequency, dysuria, and tenesmus (Sans et al, 1986). Recurrent UTIs or cystitis refractory to antibiotic therapy may suggest a colovesical fistula (Rao et al, 1987). Although it is rare for enterovesical fistulae to have sepsis as the presenting sign (Woods et al, 1988), patients with

TABLE 89-6 Causes of Vesicoenteric Fistulae*

Diverticulitis	65%-75%
Malignancy	10%-15%
Crohn disease	5%-6%
Other (trauma, appendiceal abscess, foreign body)	<5%

sepsis are found to have urinary obstruction in approximately 70% of cases (Mileski et al, 1987).

Diagnosis

Many studies exist for the diagnosis of enterovesical fistulae; however, there are significant problems with both false negatives and false positives among the diagnostic modalities, and thus the diagnosis is often made on clinical grounds. Cystoscopy has the highest yield in identifying a potential lesion, with some type of abnormality noted on endoscopic examination in more than 90% of cases (Morse and Dretler, 1974) (Fig. 89-50). However, the findings on cystoscopy are often nonspecific and include localized erythema, papillary, or bullous change; a definitive diagnosis using cystoscopy can be made in only 35% to 46% of cases (Woods et al, 1988; Pontari et al, 1992). Cystoscopy and biopsy of abnormal-appearing tissue or an established fistula tract in the setting of a history of malignancy are indicated to evaluate for the possibility of a malignant fistula.

Cross-sectional imaging, especially CT scanning, has become the imaging modality of choice (Goldman et al, 1984, 1985; Jarrett and Vaughan, 1995; Gruner et al, 2002). CT or MRI (Haggett et al, 1995) may localize the fistula tract, as well as the involved segment of bowel. The triad of findings on CT that are suspicious for colovesical fistulae consist of (1) bladder wall thickening

adjacent to a loop of thickened colon, (2) air in the bladder (in the absence of previous lower urinary manipulation), and (3) the presence of colonic diverticula (Labs et al, 1988). Labs and colleagues (1988) correctly diagnosed colovesical fistulae on CT in 11 of 12 patients with surgically confirmed lesions. CT is now generally considered to be the most sensitive and specific modality for the diagnosis of colovesical fistulae in suspect patients (Najjar et al, 2004), with diagnostic accuracy as high as 90% to 100% (Goldman et al, 1985; Jarrett and Vaughan, 1995). The high diagnostic accuracy of CT in detecting enterovesical fistulae relates to its ability to detect even a very small amount of air in the bladder (Fig. 89-51). Although air in the bladder on diagnostic imaging is very suggestive of colovesical fistulae, false positives may be created by recent instrumentation (catheterization, cystoscopy) or an active UTI with a gas-forming organism. CT scanning should be done after the administration of oral contrast but before the administration of intravenous contrast to permit detection of barium within the bladder. Ultrasonography has also been reported to be useful in the diagnosis of colovesical fistulae. A characteristic “beak” sign may be noted; however, this study is not usually performed in the routine evaluation of the patient with a suspected enterovesical fistula (Chen et al, 1990).

Although commonly used, cystography and transrectal contrast studies (e.g., barium enema) are in general less likely to demonstrate the fistula. Rao and colleagues (1987) reported that 14 of 24 barium enemas either demonstrated or were suspicious for colovesical fistulae in a series of surgically treated patients. Barium enemas and/or colonoscopy may be valuable adjunctive studies in evaluating for colonic disease, such as malignancy, as a cause of the fistula; the preoperative knowledge of such a condition can considerably alter management decisions. Nevertheless, barium enemas have limited use in the diagnosis of enterovesical fistulae owing to low sensitivity (Amendola et al, 1984). The Bourne test, however, can be a useful adjunctive study in the evaluation of colovesical fistulae (Bourne, 1964). As described, the Bourne test is performed after a nondiagnostic barium enema. The first voided urine after the barium enema is immediately centrifuged and then examined radiographically. Radiodense particles in the urine are considered a positive test result and evidence for a vesicoenteric fistula. Amendola and colleagues (1984) reported a positive Bourne test in 9 of 10 patients with colovesical fistulae; the Bourne test was the only evidence for a colovesical fistula in 7 such patients who had an otherwise negative evaluation with a combination of other diagnostic studies.

The diagnosis of vesicoenteric fistulae may be confirmed by the oral administration of activated charcoal, which, in the

setting of a fistula, will appear in the urine as black particles (Geier et al, 1972). This test provides no anatomic information regarding the location of the fistula but is useful in confirming the diagnosis in suspect cases. Intrarectal administration of vital dyes has been advocated for the diagnosis of occult colovesical fistula; however, the dye may be absorbed and then excreted in the urine, giving a false-positive test result (Deshmukh et al, 1977). Accepting the limitations of small case series in this regard, a number of studies have investigated the value of a range of investigative techniques in the detection and evaluation of enterovesical or colovesical fistulae (Amendola et al, 1984; Pollard et al, 1987; Kuhlman and Fishman, 1990; McBeath et al, 1994; Jarrett and Vaughan, 1995; Liu et al, 1999; Bernstine et al, 2002; Kavanagh et al, 2005; Garcea et al, 2006). Because in each study the authors have presented only results from patients known to have fistulae, sensitivity may be estimated; however, specificity, positive predictive value, and negative predictive value cannot. No test was shown to have consistent reliability; excluding those investigations for which only a single report was identified, CT (53%), cystoscopy (48%), and, in the case of colovesical fistula, barium enema (38%) were perhaps the most useful; IVU and sigmoidoscopy or colonoscopy appear to have limited usefulness in the diagnosis of GI fistula (De Ridder et al, 2013).

Management

Nonoperative management is a viable option in selected patients with vesicoenteric fistula. Amin and colleagues (1984) reported on 4 of 30 patients with colovesical fistulae secondary to diverticulitis who were observed without active intervention for 3 to 14 years. There were no significant long-term sequelae in this select patient population. In nontoxic, minimally symptomatic patients with nonmalignant causes of enterovesical fistulae, a trial of medical therapy including intravenous total parenteral nutrition (Dudrick et al, 1999), bowel rest, and antibiotics may be warranted. This may be the preferred initial approach, especially in patients with Crohn disease, in whom the notion of immediate exploratory laparotomy and bowel resection is often discouraged because of the chronic relapsing nature of the disease (Evans et al, 2003a). There is also the potential for successful medical management of other fistulae resulting from inflammatory bowel disease (Mahadevan et al, 2003; Parsi et al, 2004). Ileovesical fistula in Crohn disease may be managed with antibiotics, nutritional support, often including total parenteral nutrition, and various combinations of immunomodulatory agents. In a nonsystematic review of the management of internal fistulae in Crohn disease, Levy and Tremaine described the drugs that have been reported to close internal fistulae partially or completely, including azathioprine, 6-mercaptopurine, mycophenolate mofetil, cyclosporine A, tacrolimus, and infliximab (Levy and Tremaine, 2002).

One case series of 500 patients with Crohn disease included 17 with enterovesical fistulae; all received sulfasalazine, most were treated with corticosteroids and antibiotics intermittently, and 8 in addition received 6-mercaptopurine. Although it is not clear that their fistulae closed completely, 6 continued on medical treatment alone for several years (Margolin and Korelitz, 1989).

Present and colleagues reported a placebo-controlled randomized trial of the tumor necrosis factor- α (TNF- α) neutralizing agent infliximab, a murine-human chimeric monoclonal antibody that binds both the soluble subunit and the membrane-bound precursor of TNF- α , in patients with externally draining fistulae associated with Crohn disease (Present et al, 1999). Adverse events were very common, but complete resolution of all fistulae was achieved in 55%, and 50% reduction in fistulous drainage was achieved in 68% of patients on 5-mg infliximab. This study did not include ileovesical fistulae, although a case of successful use of infliximab in an ileovesical fistula has been reported (Game et al, 2003).

The goal of operative management is to separate and close the involved organs with minimal anatomic disruption and normal long-term function of both systems. Unfortunately, enterovesical fistulae may be complicated by intense pelvic inflammation, pelvic

abscess, and phlegmon formation (in some cases), requiring complex staged reconstructions (Shackley et al, 2000). Bowel resection and/or partial cystectomy may be necessary to obtain viable tissue margins to ensure adequate, watertight closure of the involved viscera. An interpositional flap of greater omentum is often placed between the repaired bowel and urinary bladder to prevent overlapping suture lines and provide a well-vascularized surface for healing.

Both single and multistage procedures have been advocated, depending on the clinical circumstances (Morse and Dretler, 1974; Castro, 1975; Ray et al, 1976; Morrison and Addison, 1983; Mileski et al, 1987; Pollard et al, 1987; Rao et al, 1987; Shackley et al, 2000; Walker et al, 2002; Najjar et al, 2004). A one-stage procedure involves removal of the fistula, closure of the involved organs, and primary reanastomosis of the bowel after resection of the involved bowel segment. A two-stage approach advocates removal of the fistula, closure of the involved organs, and creation of a temporary proximal diverting colostomy, with a later return to the operating room for colostomy takedown once the fistula tract has been demonstrated to be closed. The choice of whether to proceed with a one-stage or two-stage repair is influenced by the location and cause of the fistula, the patient's general condition, the presence of a pelvic abscess, and the presence of colonic obstruction (McConnell et al, 1980). Patients with an inflammatory cause of the fistula but without gross contamination can be treated with a one-stage procedure, whereas those with an unprepared bowel, gross contamination, or abscess may require a multistage procedure (Mileski et al, 1987; Shackley et al, 2000). As noted previously, most patients with colovesical fistulae present themselves electively with lower urinary tract symptoms, not emergently in extremis with sepsis (Mileski et al, 1987). Therefore adequate preoperative support, including bowel preparation, nutritional supplementation, and appropriate antibiotics, can be used in the majority of patients, allowing an elective one-stage approach. The authors of many case series have advocated a one-stage approach in the majority of cases but have indicated that this should be limited to patients whose nutritional state is good and in whom there is no evidence of severe inflammation, radiation injury, advanced malignancy, intestinal obstruction, major medical problem, or advanced age (McConnell et al, 1980; Mileski et al, 1987; Pollard et al, 1987; Pontari et al, 1992; McBeath et al, 1994; Hsieh et al, 1997). More recent series have tended to imply a greater advocacy of the one-stage approach; Garcea and colleagues in a series of 90 patients with colovesical fistula reported primary anastomosis in 61 of 65 (94%) cases wherein left colon resection was undertaken (Garcea et al, 2006). Balaguera and colleagues argued against diverting colostomy or Hartmann procedure as being unnecessary, and possibly bringing additional morbidity (Balaguera et al, 2006).

In addition to the aforementioned criteria, it is intuitive that the more complex a fistula tract, the more relevant a phased approach to treatment becomes. Shackley and colleagues described a series of 10 patients with highly complex fistulae involving three to six separate organs and surfaces (Shackley et al, 2000). They advocate a three-stage multidisciplinary management package, involving (1) an acute stage involving proximal defunctioning and distal drainage of both the GI and urinary tracts to isolate the fistula, together with the eradication of sepsis; (2) a recovery stage consisting of total parenteral nutrition, organ support, radiologic planning of surgical reconstruction, and intensive nursing; (3) joint urologic and GI reconstructive surgery when the patient was stable and nutritionally replenished and the sepsis was controlled. The mean time to reconstruction was 5 (1 to 20) months; the fistulae were treated successfully in all patients, with functional restoration in 4 and/or diversion of the GI and urologic tracts in 6 (Shackley et al, 2000).

Laparoscopic management of colovesical fistulae has been reported, albeit with a relatively high rate of conversion to open repair (Joo et al, 1997). Several reports have described a laparoscopic approach to one-stage treatment of colovesical fistulae, including a total of 30 patients (Serizawa et al, 1996; Menenakos et al, 2003; Pokala et al, 2005; Tsivian et al, 2006). The overall conversion rate was seen to be higher for fistulae involving the

duodenum, vagina, and sigmoid colon than for those involving the bladder (10%), although a low threshold for conversion to open surgery was advocated in one series (Pokala et al, 2005).

KEY POINTS: VESICOENTERIC FISTULAE

- The most common cause of vesicoenteric fistulae is diverticulitis.
- Presenting symptoms are usually urinary, most commonly pneumaturia.
- Diagnosis is generally made with a combination of cystoscopy and cross-sectional imaging, including a CT scan.
- Repair of colovesical fistulae involves a single-stage or multistage procedure, depending on a number of clinical factors, including the presence of gross fecal contamination and infection.

Ureteroenteric Fistula

Fistulae between the ureter and the bowel are most likely to occur in the setting of inflammatory bowel disease such as Crohn disease. The segment of bowel most likely to be involved is the terminal ileum (Banner, 1987), and thus the vast majority of ureteroenteric fistulae are unilateral and right sided (Sigel et al, 1977). Rarely, diverticulitis (Ney et al, 1986; Cirocco et al, 1994; Maeda et al, 1998) or ulcerative colitis will lead to a left-sided ureteroenteric fistula (Sigel et al, 1977). Involvement of the ureter is usually at the level of the sacral promontory (Sigel et al, 1977). Other causes of ureteroenteric fistulae include calculous disease, tuberculosis (TB), external and iatrogenic (surgical) trauma, radiation therapy, and transitional cell carcinoma (Javadpour et al, 1973; Sankaran et al, 1974; McElwee et al, 1983; Sumiya et al, 1985; Flood et al, 1992; Goetz et al, 1992; Toporoff et al, 1992; Oh et al, 2002). Unlike vesicoenteric fistulae, ureteroenteric fistulae are more likely to manifest with bowel rather than urinary symptoms. Pain may also be reported in the hip, flank, or anterior thigh.

The diagnosis can be made by retrograde pyelography, although CT and MRI are more useful. Barium contrast studies of the small bowel will often show a diseased segment of bowel but will only rarely demonstrate the fistula. Treatment involves ureterolysis and possible bowel resection. Ureteral resection is not necessary if it can be separated from the involved bowel segment and stented. Unfortunately, in many of these cases, significant renal damage has occurred before the definitive diagnosis, and thus nephrectomy may be necessary for definitive management (Sigel et al, 1977).

Pyeloenteric Fistulae

Pyelointestinal fistulae represent an epithelialized connection between the renal pelvis or collecting system of the kidney and the GI tract. Chronic inflammatory disease, such as xanthogranulomatous pyelonephritis or other infectious diseases involving the kidney or bowel, historically has been the most common cause of this condition (Schwartz et al, 1970; Greene et al, 1975; Bhargava et al, 1982; Cheate et al, 1985; Desmond et al, 1989; Yildiz et al, 1993; Majeed et al, 1997). However, iatrogenic surgical trauma, especially that related to percutaneous renal surgery and percutaneous nephrolithotomy (PCNL), has been associated with an increasing number of such fistulae (LeRoy et al, 1985; Culkin et al, 1990) (Fig. 89-52). Penetrating external trauma, malignancy, ulcer disease, ingested foreign bodies, and complex calculous disease may also result in pyeloenteric fistulae (Brust and Morgan, 1974; Mooreville et al, 1988; Blatstein and Ginsberg, 1996; Ginsberg et al, 1996; Chen et al, 2002). Right-sided pyeloenteric fistulae most often involve the duodenum owing to their close anatomic relationship, whereas left-sided pyeloenteric fistulae most commonly involve the descending colon.

Figure 89-52. Pyelocolonic fistula after cryosurgical ablation of a renal tumor. Retrograde pyeloureterogram demonstrates contrast extravasation into the colon.

The majority of patients have nonspecific symptoms, including malaise, nonspecific GI symptoms, urinary frequency, flank mass, or tenderness. Approximately 60% to 70% of patients have flank pain, fever, and pyuria (Desmond et al, 1989). Iatrogenic fistulae as a result of endourologic procedures may cause minimal symptoms. In some cases, they are noted only incidentally on postoperative nephrostogram (Culkin et al, 1990). Diagnosis can be made with a combination of urography, retrograde pyelography, and nephrostogram. The GI tract may be studied with a barium swallow or enema.

Historically, pyeloenteric fistulae were treated by nephrectomy and closure of the GI tract (Greene et al, 1975); however, given the changing nature of the cause of these lesions, in many cases the fistula may be initially treated conservatively, especially if associated with a normally functioning kidney. A large nephrostomy tube, enteric suction or bowel rest, antibiotics, and removal of any foreign body (e.g., a stone) may be attempted. Internal stenting of the urinary tract may be pursued for maximal drainage (Desmond et al, 1989). Fistulae associated with a poorly functioning kidney are best treated by primary closure of the bowel and nephrectomy. Case reports of ureterocolic fistulae occurring after renal cryotherapy and gunshot trauma all resolved with insertion of a ureteral stent (Vanderbrink et al, 2007; Ould Ismail et al, 2010). This is in line with previous accounts of this complication after PCNL (El-Nahas et al, 2006).

Urethrorectal (Rectourethral or Prostatorectal) Fistula

Acquired rectourethral fistula (RUF) may occur in the male under a variety of clinical circumstances, including those related to prostatectomy for benign or malignant disease, cryotherapy, pelvic radiotherapy, anorectal surgery, external penetrating trauma (Bukowski et al, 1995; al-Ali and Kashmoula, 1997), urethral instrumentation (Thompson and Marx, 1990), locally advanced prostatic or rectal malignancy, infection (e.g., TB) (Okanya et al, 1988), ruptured prostatic abscess, or inflammatory disease (e.g., Crohn disease) (Stamler et al, 1985; Fazio et al, 1987). Congenital RUF associated with imperforate anus is covered in Chapter 128.

Etiology and Presentation

The incidence of RUF after radical retropubic prostatectomy (RRP) is low, but owing to the frequency with which the

operation is performed, it is the most common cause of RUF in most modern series (Stephenson and Middleton, 1996; Nyam and Pemberton, 1999; Renschler and Middleton, 2003). Rectal injury during radical prostatectomy occurs in less than 1% to 2% of patients (Igel et al, 1987; Borland and Walsh, 1992; McLaren et al, 1993; Guillonnet et al, 2003). In a Mayo RRP series, there were 27 documented rectal injuries in 2212 patients (McLaren et al, 1993). In this series, 26 of 27 injuries were recognized intraoperatively and repaired. Six patients underwent temporary colostomy, and 4 patients developed RUF. In a community-based practice, Harpster and colleagues (1995) reported rectal injuries in 7 of 516 patients undergoing RRP (1.4%) and in 1 of 17 patients undergoing radical perineal prostatectomy (Harpster et al, 1995). Five rectal injuries were recognized and repaired intraoperatively. There were 3 RUFs reported in this series; none closed with conservative management, and all required formal repair. Rassweiler and colleagues (2003) reported 1 RUF in a series of 219 patients undergoing RRP but 7 RUFs in 538 patients undergoing laparoscopic radical prostatectomy. All operations were performed by the same surgical team. Guillonnet and colleagues (2003) reported a 1.3% incidence of rectal injury in 1000 consecutive patients undergoing laparoscopic radical prostatectomy. Eleven of 13 injuries were recognized and repaired intraoperatively with a two-layer closure. One of these patients subsequently underwent temporary colostomy for complications related to the injury. Both patients with rectal injuries that were recognized postoperatively underwent colostomy. One of the 2 patients with a lately recognized rectal injury developed an RUF requiring a primary surgical closure.

In the setting of radical prostatectomy, a prior history of pelvic radiation therapy, rectal surgery, or transurethral resection of the prostate (TURP) is associated with an increased risk of RUF (Thompson and Marx, 1990; McLaren et al, 1993). RUF that occurs after radical prostatectomy is usually seen at the vesicourethral anastomosis and is often caused by an unrecognized rectal injury at the time of surgery. However, when a rectal injury is recognized and repaired intraoperatively, RUF is extremely uncommon. Borland and Walsh reported 10 rectal injuries in 1000 nonirradiated patients undergoing radical prostatectomy at Johns Hopkins Hospital; however, no patient developed a RUF (Borland and Walsh, 1992). Nine of 10 patients had a two-layer closure performed with an omental interpositional flap at the time of injury. One patient underwent a temporary diverting colostomy; the rectal injury was diagnosed and repaired on postoperative day 2. Anal sphincter dilation was performed on all patients, and they received 7 to 14 days of postoperative antibiotics.

The reported incidence of RUF after cryosurgical ablation as primary therapy for localized carcinoma of the prostate is 0.5% to 2% (Zippe, 1996; Long et al, 2001), whereas the rate of RUF after cryotherapy as salvage therapy for prostate cancer is somewhat higher at approximately 3.3% (Chin et al, 2001). The incidence of RUF after brachytherapy for prostate cancer as reported by Theodorescu and colleagues (2000) is 0.4%. RUFs have also been reported to follow high-intensity focused ultrasound (HIFU) treatment (Uchida et al, 2002; Blana et al, 2004), HIFU combined with external beam radiotherapy (6% incidence) (Gelet et al, 2004), laparoscopic radical prostatectomy (Guillonnet et al, 2003; Katz et al, 2003; Rassweiler et al, 2003; Dafnis et al, 2004), and transurethral thermotherapy for benign prostatic hyperplasia (BPH) (Norby and Frimodt-Moller, 2000). The incidence of RUF in Crohn disease is estimated to be approximately 0.3% (Stamler et al, 1985) (Fig. 89-53). Fistulae caused by Crohn disease are complex, and management should be individualized (Stamler et al, 1985; Fazio et al, 1987; Santoro et al, 1995; Cools et al, 1996; Rius et al, 2000).

The presentation of RUF is variable. Symptoms may include fecaluria, hematuria, UTI, nausea, vomiting, and fever. Peritonitis and sepsis may occur as well. Digital rectal examination often permits palpation of the fistula tract along the anterior rectal wall. Cystoscopy and sigmoidoscopy (Shin et al, 2000) visualize the fistula tract in the vast majority of cases and provide a mechanism for biopsy. In patients with a history of pelvic malignancy, biopsy of the fistula is suggested to evaluate for a local recurrence

Figure 89-53. Rectourethral fistula caused by Crohn disease. Contrast material is seen posterior to the bladder on this voiding image from voiding cystourethrogram. (Courtesy Nancy Curry, MD, Department of Radiology, Medical University of South Carolina, Charleston, SC.)

Figure 89-54. Rectourethral fistula after brachytherapy for carcinoma of the prostate. A retrograde urethrogram demonstrates filling of the rectum in this patient who was seen several years after brachytherapy with fecaluria. The bladder is not opacified. The brachytherapy seeds can be seen in the area of the prostate.

of the tumor (Shin et al, 2000). A VCUG or retrograde urethrogram (RUG) usually provides a definitive diagnosis of RUF (Fig. 89-54). The exact anatomic location and size of the fistula are also usually well delineated on the VCUG or RUG, providing important information in surgical planning. Lateral projections may be necessary to visualize small fistulae, because contrast in the rectum or urethra can sometimes obscure extremely thin fistulous tracts. Upper tract imaging should be performed in patients with RUF to exclude a

related ureteral injury. It is important to make an assessment of continence and sphincteric function in patients with RUF after radical prostatectomy. Given the location of most RUFs at or near the vesicourethral anastomosis and the membranous urethra, there is a risk for persistent severe stress incontinence postoperatively after RUF repair (Ghoniem et al, 2008). In many patients with RUF and severe stress incontinence, closure of the RUF may not be sufficient to bring about continence. Additional procedures may be needed to bring about a satisfactory result in these patients; this is an important issue to discuss in preoperative patient counseling.

Management

Most RUFs will require surgical repair (Bukowski et al, 1995; Stephenson and Middleton, 1996), although it is clear that some will close with conservative management. RUF that follows open or laparoscopic prostatectomy may heal spontaneously with catheter drainage, bowel rest, and intravenous hyperalimentation. In some cases, fecal diversion is necessary. Rassweiler and colleagues (2003) reported that 6 of 8 RUF patients were treated successfully in such a manner. Two patients required a temporary colostomy. Noldus and colleagues (1999) reported closure with conservative management in 7 of 13 patients with RUF after radical prostatectomy or cystoprostatectomy. Successful closure in 6 patients eventually was accomplished with a transanal Latzko procedure (see later). Successful minimally invasive management has been reported, as well, with use of endoscopic suturing, fulguration of the fistula tract, and the application of fibrin glue (Wilbert et al, 1996).

Surgical repair of RUF can be challenging, and the basic tenets of operative fistula repair are especially relevant in these cases (see Box 89-2). Several surgical approaches have been advocated and are outlined later. **Single and staged repairs have been described for the repair of RUF.** The controversy surrounding the staged repair centers on the issue of whether or not to perform fecal diversion at all, or whether to perform it before or at the time of repair of the urinary tract. Some authors have advocated fecal diversion and staged repair of all RUFs (Shin et al, 2000). This is considered the standard conservative approach and, in combination with an indwelling urethral catheter, permits a trial of spontaneous healing of the fistula without open manipulation of the urinary tract. In support of the single-stage repair, a successful one-stage approach limits the potential morbidity and cost of multiple procedures that, by design, accompany the staged repair. **Suggested guidelines for cases in which a one-stage approach might be appropriate include surgically induced, small RUFs not associated with infection, an abscess, or a poor bowel preparation (Wood and Middleton, 1990; Nunoo-Mensah et al, 2008).** Staged repairs might be considered in cases of large fistulae, those associated with radiation therapy, uncontrolled local or systemic infection, immunocompromised states, or inadequate bowel preparation at the time of definitive repair (Stephenson and Middleton, 1996; Nunoo-Mensah et al, 2008).

Transrectal approaches with and without division of the anal sphincter have been described for the operative repair of RUF. The York-Mason procedure is a transrectal, transsphincteric approach that has been found to be effective and to have low morbidity (Henderson et al, 1981; Prasad et al, 1983; Wood and Middleton, 1990; Stephenson and Middleton, 1996; Fengler and Abcarian, 1997; Renschler and Middleton, 2003). Classically, this is a staged repair with fecal diversion performed before repair of the RUF. However, in patients with small, nonirradiated fistulae, a single-stage approach can be used, provided that a vigorous bowel preparation and broad-spectrum antibiotics are used (Renschler and Middleton, 2003). For repair of the urinary tract, the patient is placed prone on the operating room table in the jackknife position. A full-thickness incision through the posterior anus and dorsal rectal wall is performed and deepened down to the level of the coccyx through the external anal sphincter (Fig. 89-55). Care is taken to mark or tag each layer of the anal sphincter as it is divided. Later in the procedure during closure, careful anatomic

reapproximation of the layers of the external anal sphincter is necessary to avoid the devastating complication of anal incontinence postoperatively. The anorectal incision as described provides excellent exposure of the fistula in the anterior rectal wall. The fistula tract is excised, and the anterior rectal wall is mobilized circumferentially around the fistula margins. The urethra is closed, and then the anterior rectal wall is closed. Finally, the rectal mucosa is reapproximated, providing a three-layer closure. Alternatively, after excision of the RUF, an anterior rectal wall flap can be developed and advanced over the fistula (al-Ali and Kashmoula, 1997), similar to the transvaginal repair of VVF using the vaginal wall (see previous discussion under VVF repair). Closure of the incision is performed by reapproximating the posterior rectal wall and then sequentially closing the layers of the anal sphincter in an anatomic fashion. Results with the York-Mason procedure have been excellent. In the largest series of patients undergoing the York-Mason procedure, Renschler and Middleton (2003) reported a successful repair in 22 of 24 patients. One of the two failures was subsequently repaired with another York-Mason procedure. No serious complications were reported, and no patient developed anal incontinence or anal stenosis. Similar excellent results have been noted by other authors (Prasad et al, 1983; Bukowski et al, 1995; Fengler and Abcarian, 1997).

In contrast to the transrectal, transsphincteric approach, the **transanal approach** to RUF repair does not involve division of the anal sphincter. Exposure of the fistula is provided by dilation of the anus and fixed retraction. The Latzko procedure is one such approach (Noldus et al, 1999; Hata et al, 2002). Similar to the Latzko method described previously for transvaginal VVF repair (see prior discussion), the fistula tract and surrounding rectal mucosa are denuded in all four quadrants. The fistula is then closed in three layers. The major disadvantage to this approach is the relatively poor exposure and lack of maneuverability within the operative field. Rectal advancement flaps have also been used to successfully treat RUF through a transanal approach (Fazio et al, 1987; Dreznik et al, 2003; Garofalo et al, 2003).

A **perineal approach** to RUF has been advocated by some authors in selected cases of RUF (Bukowski et al, 1995; Nyam and Pemberton, 1999; Youssef et al, 1999; Zmora et al, 2003). Anatomically, this is a familiar approach for many urologists and has the added advantage of local access to a variety of potential interpositional flaps. Excellent results have been obtained with the perineal approach in combination with an interpositional flap, including gracilis muscle (Ryan et al, 1979; Rius et al, 2000; Zmora et al, 2003; Ghoniem et al, 2008; Gupta et al, 2008), pedicled Dartos muscle (Venable, 1989; Youssef et al, 1999; Yamazaki et al, 2001; Varma et al, 2007), penile skin (Morgan, 1975), levator muscle (Goodwin et al, 1958), and bladder (Kokotas and Kontogeorgos, 1983). Transabdominal approaches to RUF have been described with limited success (Bukowski et al, 1995; Nyam and Pemberton, 1999; Shin et al, 2000). The principal advantage of this technique is the availability of greater omentum for an interpositional flap. Potential disadvantages include the morbidity and prolonged postoperative convalescence associated with a laparotomy incision, poor exposure of the operative field (with limited maneuverability in the deep pelvis), and the risk of urinary and fecal incontinence.

The repair of RUF after external beam radiotherapy (Chrouser et al, 2005), combined radiotherapy (Marguet et al, 2007), brachytherapy (Lane et al, 2006), or cryosurgical ablation of the prostate can be especially difficult (Izawa et al, 2000; Elliott et al, 2006). These fistulae may be large and are associated with considerable induration, fibrosis, and ischemia for a variable distance around the fistula, limiting reconstructive options. Urinary reconstruction may not be possible in some of these cases, necessitating urinary diversion. Moreira and colleagues (2004) reported on 11 cases of RUF after brachytherapy for the treatment of prostate cancer; all of these patients underwent diverting colostomy. Three patients with satisfactory baseline continence underwent primary repair by a York-Mason approach with a gracilis flap; 7 patients underwent urinary diversion combined with radical pelvic surgery (6 cystoprostatectomy, 1 prostatectomy); and 1 refused repair. Izawa and colleagues

Figure 89-55. Diagram of York-Mason approach to the repair of rectourethral fistula. (From Middleton RG. Rectourethral fistula repair. In: Krane RJ, Siroky MB, Fitzpatrick JM, editors. *Operative urology*. Philadelphia: Churchill Livingstone; 2000. p. 286.)

(2000) reported on the management of severe complications of cryosurgical ablation of the prostate, including two cases of prostatopubic fistulae and one RUF. Two of these patients underwent cystoprostatectomy, and one had a bladder neck closure and continent reconstruction.

KEY POINTS: RECTOURETHRAL FISTULA

- Rectourethral fistula is an uncommon outcome that results most commonly from the surgical treatment of localized prostate cancer.
- Diagnosis of RUF can be confirmed with VCUG.
- Treatment of RUF most commonly involves surgical repair; however, select patients may respond to conservative therapy, including Foley catheter drainage.

UROVASCULAR FISTULAE

Fistulae between the urinary tract and the vascular system are rare but have increased in frequency with the rapid integration of minimally invasive interventions in the upper urinary tract, such as percutaneous access procedures (Clayman et al, 1984; Segura et al, 1985) and indwelling ureteral stents (Kar et al, 1984; Smith, 1984; Teuton et al, 1987; Sacks and Miller, 1988; Cass and Odland, 1990). These fistulae include communications between the upper urinary tract, including the collecting system or ureter, and an artery or vein.

Renovascular and Pyelovascular Fistulae

The most common causes of renovascular or pyelovascular fistulae are procedures in which percutaneous renal access is required, such as PCNL (Clayman et al, 1984; Segura et al, 1985; Lang, 1987; Lee et al, 1987). Typically, these fistulae are created through puncture of an intrarenal vascular structure during creation or dilation of the nephrostomy tract. The damaged vessel may bleed on puncture or may not hemorrhage immediately owing to external compression and tamponade from the catheter in the nephrostomy tract. However, on removal of the catheter, brisk bleeding may be noted into the relatively lower-pressure renal collecting system (Patterson et al, 1985). Alternatively, a long-term indwelling nephrostomy tube may lead to pyelovascular fistula formation. In this setting, a chronic indwelling large-bore nephrostomy tube may result in erosion into an adjacent renal vessel with resulting hemorrhage on removal of the tube. Lee and colleagues (1987) reported an 11.2% incidence of bleeding requiring transfusion and 1.2% incidence of bleeding requiring surgical or angiographic intervention after PCNL in 582 patients. Patterson and colleagues (1985) reported a vascular injury in 0.9% of 1032 patients undergoing percutaneous renal stone surgery. Segura and colleagues (1985) reported a 3% transfusion rate in 1000 patients undergoing PCNL. Other causes of renovascular fistula include external penetrating and blunt trauma (Stower et al, 1989), infection, and open renal surgery, including partial nephrectomy.

Patients with renovascular fistulae may have life-threatening hemorrhage and hypovolemic shock, or intermittent gross hematuria. After PCNL these fistulae may appear on removal of the nephrostomy tube with brisk bleeding out of the flank from the

nephrostomy tube tract in combination with brisk hematuria, or they may manifest several days to weeks later with only hematuria (Clayman et al, 1984; Patterson et al, 1985).

Treatment of renovascular fistulae is contingent on the presentation, cause, and hemodynamic stability of the patient. Patients with severe hemorrhage on removal of the nephrostomy tube can be temporized in some instances by replacing the tube, or, in large mature tracts, by placing a Foley catheter to tamponade the bleeding. In patients with ongoing bleeding, transcatheter angiographic embolization of the lacerated vessel is recommended (Clayman et al, 1984; Patterson et al, 1985). Occasionally, flank exploration is necessary with partial or simple nephrectomy to control hemorrhage.

Uterovascular Fistula

Rarely reported before the advent of indwelling ureteral stents, uterovascular fistulae are becoming increasingly common. Most reported uterovascular fistulae are ureteroiliac artery fistulae, although ureteroiliac vein fistulae have been reported as well (Teuton et al, 1987). Ureteroarterial fistulae are extremely rare, with few cases reported in the literature (Holmes et al, 1998; Georgopoulos et al, 2003).

Most cases of ureteroarterial fistulae are reported in patients with a prior history of vascular disease, radiation therapy, and/or pelvic surgery, especially in the setting of indwelling ureteral stents. In fact, ureteroarterial fistulae are highly associated with indwelling stents (Nelson and Fried, 1981; Kar et al, 1984; Smith, 1984; Bhargava and Yusuf, 1987; Sacks and Miller, 1988; Cass and Odland, 1990; Batter et al, 1996; Bergqvist et al, 2001). Of the 37 cases of ureteroarterial fistula before 1996 reported in the literature by Batter and colleagues (1996), 24 were associated with a ureteral stent (Table 89-8 on the Expert Consult website). All patients in this review had at least one of the risk factors listed in Table 89-8 on the Expert Consult website. Pressure necrosis from a chronic, relatively inflexible indwelling stent against a pulsatile iliac artery may be an important factor in the development of ureteroarterial fistulae in some cases (Batter et al, 1996). Fistula formation occurs between the high-pressure vascular lumen and the low-pressure ureter with the development of gross hematuria. A history of radiation therapy or prior pelvic surgery may exacerbate the already compromised and stented ureter, thus increasing the risk of fistula formation (Toolin et al, 1984). Ureteroarterial fistulae are also highly associated with vascular pathology such as iliac artery aneurysms. Atherosclerotic aneurysms may produce perivascular inflammation and fibrosis that entraps the overlying ureter, especially in the region of the iliac vessels. The ureter may become fixed and obstructed and in such a position may be subject to chronic pulsations from the underlying abnormal vessel. Placement of a ureteral stent to relieve the obstruction may further compromise the ureteral wall where it crosses over the vessel, resulting in pressure necrosis and eventual fistula formation (Sacks and Miller, 1988; Cass and Odland, 1990). Ureteroarterial fistulae have been reported after balloon dilation of ureteral strictures (Sacks and Miller, 1988; Quillin et al, 1994). Ureteroarterial fistulae may also occur in the setting of ileal conduit reconstruction, pelvic malignancy, prior ureterolithotomy, external penetrating trauma, and pregnancy (Reiner et al, 1975; Cass and Odland, 1990; Dervanian et al, 1992; Puppo et al, 1992; Wampler et al, 1992; Batter et al, 1996; DePasquale et al, 2001; Siablis et al, 2002; Takahashi et al, 2004).

Uterovascular fistulae may manifest with microscopic hematuria, intermittent gross hematuria, or life-threatening exsanguinating hemorrhage. The key to the diagnosis of ureteroarterial fistulae is a high index of suspicion in an at-risk patient with gross hematuria (Smith, 1984; Dervanian et al, 1992; Batter et al, 1996). These fistulae are rarely considered in the initial differential diagnosis of gross hematuria. Intermittent gross hematuria or the sudden onset of massive hematuria in a patient with an indwelling stent and a history of previous iliac artery surgery or radiation should raise the suspicion of a ureteroarterial fistula (Cass and Odland, 1990).

The routine urologic and radiologic evaluation of hematuria will not generally provide evidence of ureterovascular fistula (Quillin et al, 1994). Even in suspected or proven cases, preoperative radiologic investigations, including nonselective arteriography and pyelography, are often nondiagnostic (Cass and Odland, 1990; Batter et al, 1996). This is especially true in patients with intermittent hematuria in whom there is no active bleeding at the time of the radiographic investigation, presumably because of thrombus over the site of the fistula. Selective or subselective arteriography of the iliac vessels may be more revealing in suspected cases, and provocative maneuvers, such as stent removal, or mechanical friction of the ureteral lumen by manipulation of the stent may be necessary to demonstrate the fistulous connection in patients without active bleeding who are undergoing angiography (Keller et al, 1990; Quillin et al, 1994). However, these adjuvant maneuvers should be performed only with extreme caution in an appropriate setting where immediate angiographic or surgical intervention is possible. In the review by Batter and colleagues (1996), retrograde pyelography was diagnostic for only 6 of 10 patients in whom it was performed, and arteriography was diagnostic for a ureterovascular fistula in only 4 of 14 cases. Indirect evidence of a ureteroarterial fistula can be found on CT, but findings are usually nonspecific and only suspicious in retrospect after a confirmed diagnosis achieved by other means (Baum et al, 1987; Jafri et al, 1987). Nevertheless, in a stable patient with a suspected ureterovascular fistula, a full radiographic evaluation may be pursued, not only for diagnostic purposes but also to evaluate potential reconstructive options (Batter et al, 1996) and, in select cases, to perform therapeutic angiographic embolization procedures.

Because these patients may be in extremis with hypotension and severe hemorrhage, surgical intervention must be considered early, especially because radiographic evaluation may be nondiagnostic (Dervanian et al, 1992). In cases in which angiography is pursued for diagnosis, an endovascular stent graft may be placed (Bergqvist et al, 2001; Sherif et al, 2002; Krambeck et al, 2005; Meester et al, 2006; Muraoka et al, 2006; Ishibashi et al, 2007; Araki et al, 2008).

Eventual management of these fistulae must address both the vascular and the urinary sides of the fistula. Successful management of the vascular side may involve embolization, endovascular stent graft placement, primary repair (Kar et al, 1984), or even ligation with or without extra-anatomic vascular bypass. Limb salvage is an important consideration in iliac artery fistulae, and therefore vascular surgery consultation is necessary in most cases. Ultimate management of the vascular side of the fistula is dependent on several factors, including the presence of infection or abscess, presence of aneurysm or occlusive disease in the iliac artery, and the availability of collateral circulation to the ipsilateral lower extremity (Batter et al, 1996). Often, vascular occlusion, either angiographically or surgically, is followed by vascular bypass procedures in these cases. A systematic literature review found reports of 139 cases of ureteroarterial fistula published from 1899 to 2008 (van den Bergh et al, 2009). All patients had hematuria, with 25% also having other urinary symptoms or back pain. Virtually all patients had a relevant past surgical history, particularly pelvic cancer surgery (54%) and arterial surgery with graft insertion (31%), and 61% had a ureteric stent in situ. The great majority affected the iliac segment, and preoperative imaging was not always diagnostic. A total of 18 (13%) patients died as a result of the fistula. Many vascular and urologic interventions were used either alone or in combination. Later cases suggested that endovascular repair of the arterial defect gave the best results with lower mortality. Another, more recent case series of 20 patients also showed a high mortality of 10% to 20% but did not find any difference in outcome between open or endovascular graft insertion techniques (Fox et al, 2009).

Repair and reconstruction of the urinary tract is complicated in these patients, who often have a history of pelvic irradiation, malignancy, vascular disease, and/or prior surgery. Preservation of nephrons is a priority in functioning renal units. Urinary

TABLE 89-8 Predisposing Risk Factors in 37 Patients with Ureteroarterial Fistulae

Prior genitourinary or pelvic surgery	68%
Ureteral stenting	65%
Radiation therapy	46%
Prior vascular surgery	19%
Vascular pathology	19%

From Batter SJ, McGovern FJ, Cambria RP. Ureteroarterial fistula: case report and review of the literature. *Urology* 1996;48:481–9.

reconstruction can be performed by ureteroureterostomy, trans-ureteroureterostomy, cutaneous ureterostomy, or percutaneous nephrostomy with ureteral ligation (Nelson and Fried, 1981; Kar et al, 1984; Smith, 1984; Batter et al, 1996; Gibbons et al, 1998). Nephrectomy is usually reserved for poorly functioning kidneys or for patients unfit for urinary reconstruction.

General recommendations to prevent ureteroarterial fistulae include the use of the smallest, softest, and most flexible ureteral stents for the shortest time interval possible in patients at risk for ureterovascular fistula (Cass and Odland, 1990; Puppo et al, 1992).

KEY POINTS: UROVASCULAR FISTULAE

- Pyelovascular fistulae most commonly result from percutaneous interventional procedures to the upper urinary tract.
- Patients with suspected ureteroarterial fistulae usually have one or more risk factors including a history of pelvic radiotherapy, indwelling ureteral stents, prior pelvic surgery, and/or vascular disease.
- Ureteroarterial fistulae are difficult to diagnose radiographically with standard imaging, including CT scan and retrograde pyelography.
- Patients suspected of having a ureteroarterial fistula based on history and the presence of significant risk factors should be treated expeditiously and aggressively on presentation.

OTHER URINARY FISTULAE

Urinary fistulae have been reported between the kidneys and thoracic cavity with a number of causes, including infection, trauma, and stone disease. Infectious causes include xanthogranulomatous pyelonephritis, TB, and renal abscess (Arida and Verderame, 1977; Blight, 1980; Kyriakopoulos et al, 1991; Haney et al, 1992; Alifano et al, 1999). Fortunately, nephropleural and nephrobronchial fistulae are uncommon. Of importance, percutaneous access to the kidney for endourologic procedures may be complicated by nephropleural fistula. Lallas and colleagues (2004) reported a 1% incidence of nephropleural fistulae in 375 patients undergoing percutaneous access procedures. All of the affected patients had a supracostal access tract performed; none of the patients with a subcostal access tract developed this complication. Presenting symptoms may include cough, a urine-like taste in the mouth, fever, and flank pain. Rarely, recurrent lung abscess may be a manifestation of an occult nephropleural fistula (Caberwal et al, 1977; O'Brien and Ettinger, 1995).

Treatment of nephropleural or nephrobronchial fistulae typically involves percutaneous drainage of any associated abscess (if present), treatment of associated infection, and/or urinary obstruction, and surgical exploration with interposition of healthy tissue. Iatrogenic fistulae resulting from percutaneous access procedures can be managed nonoperatively in some cases (Lallas et al, 2004). For patients undergoing surgical exploration, a double-lumen endotracheal tube may be useful during surgery to isolate the affected lung and pleural cavity and prevent contamination of the contralateral side (Rao et al, 1981). Nephrectomy is indicated in poorly functioning renal units.

Cutaneous fistulae from the urinary tract may arise from the kidney, ureter, bladder, or urethra. Renocutaneous fistulae may occur as a result of chronic infection, especially in the setting of calculous disease (Haney et al, 1992). Often the associated renal unit is poorly functioning, and thus definitive treatment is provided by nephrectomy. External trauma or iatrogenic surgical trauma, such as percutaneous renal surgery or partial nephrectomy, may also result in a renocutaneous fistula. Prompt treatment with internal ureteral stenting is usually successful by providing unobstructed antegrade urinary drainage. Most ureterocutaneous and vesicocuta-

neous fistulae are iatrogenic or otherwise purposefully surgically created to facilitate urinary drainage. Other uncommon causes include external penetrating trauma, malignancy, and chronic infection.

For newly diagnosed urocutaneous fistulae, it is imperative to evaluate for distal urinary obstruction. If present, the obstruction should be treated, if possible, or bypassed. Individuals with non-healing urocutaneous fistulae caused by chronic infection not only should be evaluated for an occult source of the infection, but also should undergo a nutritional evaluation because these individuals may be catabolic, immunosuppressed, and unable to mobilize adequate metabolic reserves to initiate wound closure. Other considerations in individuals with nonhealing urocutaneous fistulae include occult malignancy or an undiscovered foreign body.

Urethrocuteaneous fistulae in the male most commonly are seen as sequelae of hypospadias repair and are covered in Chapter 130.

Urinary Leak after Renal Preservation Surgery

A large case series identified urinary fistula, defined as urinary drainage from a drain site more than 14 days postoperatively, in 4% (45 of 1118) of patients undergoing partial nephrectomy (Kundu et al, 2010). This was associated with larger tumors, greater blood loss, and longer ischemia time, but not the mode of surgery (laparoscopic vs. open). The majority resolved without intervention, but 30% required ureteral stent insertion or percutaneous drainage. A poor-quality quasi-randomized study involving 16 patients with persistent leakage after pelvic cystectomy despite stenting found that use of intranasal desmopressin 40 µg daily resulted in a shorter time to resolution of leak compared with controls (Razzaghi et al, 2009).

Urinary Leak after Renal Transplantation

A case series from Brazil observed a fistula rate of 3.0% (31 of 1046) at a mean of 28 (1 to 131) days after transplantation, predominantly as a result of distal ureteral necrosis and with most cases requiring open repair (Mazzucchi et al, 2006). Fistula occurred more commonly in patients with diabetes and was associated with lower graft survival and 2 deaths from sepsis. A case series from China observed fistula development in 3.5% (43 of 1223) of patients at a mean of 6 (range 3 to 20) days after transplantation, again primarily a result of necrosis of the distal transplanted ureter (Nie et al, 2009). Open intervention with reimplantation of the ureter into the bladder or native ureter was required in 34 patients, with 1 other patient requiring transplant nephrectomy. The occurrence of a fistula did not appear to prejudice graft or patient survival. Initial implantation of the transplant ureter into the native ureter appeared to result in a lower rate of fistula. A further case series from Serbia found a fistula rate after renal transplantation of 2.2% (5 of 224), and all required open repair (Basić et al, 2011).

Radiation Fistula

Injury to the GI or urinary tract may arise after therapeutic radiation, with the incidence of complications increasing when the dose exceeds 50 Gy. The obliterative endarteritis associated with ionizing radiation in therapeutic doses may proceed over many years and may result in fistula formation long after the primary malignancy has been treated (Zoubek et al, 1989; Hilton, 2012). The associated devascularization in the adjacent tissues means that conventional surgical repair has a high likelihood of failure and may also result in re-presentation with several fistulae over a period of many years. If abdominal repair surgery or urinary diversions are undertaken, a high risk of GI anastomotic leak and progressive sepsis has been reported, perhaps related either to inadequate resection of irradiated bowel or to damage to other organs at operation (Cochrane et al, 1981). All these factors often make the management of post-radiation fistulae more challenging than that of postsurgical or even obstetric fistulae. Modified surgical techniques are often required, and indeed, where the same techniques have been applied to both

surgical and postradiation fistulae, the results from the latter have been consistently poorer (Hedlund and Lindstedt, 1987; Langkilde et al, 1999; Jovanovic et al, 2010). Spontaneous healing seems rarely if ever to occur (Ralph et al, 1990; Hilton, 2012) and only one case report was identified, of presentation of a radiation fistula 22 years after initial treatment, in which healing occurred after cauterization (for biopsy) and prolonged catheter drainage (Madjar and Gousse, 2001).

Diversion Procedures

Because of the wide field abnormality surrounding many radiotherapy-associated fistulae, several authors have suggested that urinary and/or fecal diversion should be seen as the treatment of choice in such cases (Jones et al, 1984; Krause et al, 1987; Emmert and Kohler, 1996; Langkilde et al, 1999). Others have employed a routine policy of preliminary urinary and fecal diversion, with later undiversion in selected cases (Vanni et al, 2010). In a nonrandomized cohort of rectourethral fistula repairs, Vanni and colleagues reported 100% closure at first operation in 35 nonirradiated patients, compared with 84% in 39 irradiated patients (Vanni et al, 2010). In addition, 97% of the nonirradiated patients subsequently underwent undiversion, whereas 31% of the irradiated patients required permanent fecal diversion because of a noncompliant rectum or severe sphincter dysfunction (Vanni et al, 2010).

Some authors have emphasized the place of repair in carefully selected cases of radiotherapy-associated fistulae (Hilton, 2012). Of 36 radiation-associated or malignant fistulae in the series reported by Hilton, although 11 patients declined surgery or died before treatment and 6 underwent primary diversion, of the 19 (53%) who underwent repair, closure was achieved in 18 (95%) at first operation (Hilton, 2012). Finally, some authors seem to take the view that diversion has little or no place in the management of radiation-induced VVF in particular (Pushkar et al, 2009). Of 216 radiation-induced fistulae managed over a 47-year period by Pushkar and colleagues, 210 patients underwent a vaginal and 6 an abdominal repair procedure (it should be noted that this is a retrospective case series, and although not stated in the paper, it is possible that other patients not included in this review actually underwent diversion) (Pushkar et al, 2009). It should be noted, however, that with this almost exclusive use of the vaginal repair procedure, although a cumulative closure rate of 80% was eventually achieved after four or more operations, closure was achieved in only 48% after first repair, in 40% after a second operation, in 52% after a third operation, and in 35% after a fourth operation.

In view of the anastomotic problems associated with radiation-induced fistula, the transverse colon has often been favored over ileum as a conduit in this context, to avoid the risk of employing irradiated bowel and distal ureter (Schmidt et al, 1975; Kisner and Kesner, 1987; Ravi et al, 1994). Although these benefits seem clear, it should be noted that high perioperative morbidity (37%) and reoperation rates (20%) have been reported from this procedure (Ravi et al, 1994).

As an alternative to the latter operation, wherein both urinary and fecal diversion are proposed, Hampson and colleagues described the technique of left colic urinary diversion with distal transverse end colostomy (Hampson et al, 1994). This technique allows a shorter operative time and avoids the necessity for an intestinal anastomosis. In patients wishing to remain sexually active after such procedures, the residual bladder or rectal wall may be used to augment the vagina (Leissner et al, 2000). Where VVF coexists with significant bladder contracture after surgery or radiation, an abdominal (transperitoneal) repair might be considered, along with simultaneous ileocystoplasty (Hsu et al, 2002; Tabakov and Slavchev, 2004) or colocystoplasty (Kulkarni and Gulla, 1998). Fistula repair performed concurrently with vaginal reconstruction using sigmoidovaginoplasty has also been described by Verbaeys and colleagues (2007). Although one might anticipate very high operative and postoperative morbidity from such complex multiple procedures, the outcome in the very small numbers reported appears to have been good.

Repair Techniques

Several different techniques for the vaginal repair of fistulae have been reported, although the methods of flap-splitting or dissection and repair in layers (variously attributed to Hayward, Collis, and Lawson Tait) (Wall, 2005) and partial colpocleisis (Latzko, 1942) have been the most widely advocated in radiation-associated fistulae. When patients do not wish to maintain sexual function, complete colpocleisis may be used to good effect (Hilton, 2012). In a nonrandomized cohort study, Hilton reported anatomic closure by colpocleisis in 94.7% of patients with radiation-associated fistulae, compared with 96.1% for a range of repair procedures in fistulae of surgical cause (Hilton, 2012).

The technique of sigmoid exclusion or isolation has been described for the management of radiation-associated colovesical or enterovesical and colovaginal or enterovaginal fistulae (Aitken and Elliot, 1985; Levenback et al, 1994). Although the results have generally been good, with the avoidance of a permanent urinary or fecal stoma, Levenback and colleagues reported poorer results than after resection of the affected bowel, largely related to bleeding from the isolated segment and bacterial infection (Levenback et al, 1994).

The interpositional grafts mentioned earlier are particularly useful in radiation-induced fistula.

Please see the Expert Consult website for further details.

Other Management Approaches

In patients with intractable urinary incontinence from radiation-associated fistula, percutaneous nephrostomy or ureterostomy might be considered (Krause et al, 1987). This may in some cases extend life perhaps inappropriately, and where life expectancy is deemed to be very short, ureteral occlusion might be more appropriate. Several methods have been described, including the insertion of coils (Amsellem-Ouazana et al, 2006), coils with gelatin sponge (Farrell et al, 1997; Gaylord and Johnsrude, 1989), clips (Farrell et al, 1997), nylon plugs with injection of polidocanol (Kinn et al, 1986), isobutyl-2-cyanoacrylate (Schild et al, 1994), and balloons (Papanicolaou et al, 1985; Sanchez et al, 1988; Schild et al, 1994; Horenblas et al, 2000). These were reviewed by Avritscher and colleagues with success rates ranging from 50% to 100% for the different methods, and with an overall success rate of 77% in 150 cases from nine papers reviewed (Avritscher et al, 2004).

Recommendations

Although diversion is used more widely in radiation-associated fistulae of all types as compared with nonirradiated fistulae, there is low-level evidence that repair procedures can achieve successful fistula closure and continence in appropriately selected cases.

Where urinary and/or fecal diversions are required, attempts should be made to avoid using irradiated tissues whenever possible and to minimize the potential for anastomotic complications.

There is low-level evidence to support the use of interpositional grafts when repair of radiation-associated fistula is undertaken.

In patients with intractable urinary incontinence from radiation-associated fistula in whom life expectancy is very short, ureteral occlusion might be considered; there is insufficient evidence to recommend any particular technique.

KEY POINTS: OTHER FISTULAE

- Nephropleural or nephrobronchial fistulae are uncommon and may occur secondary to percutaneous access procedures to the upper urinary tract.
- Urocutaneous fistulae may originate from multiple locations within the urinary tract.

Several techniques have been described to reinforce fistula repair in different sites depending on the type of repair undertaken. These include the Martius bulbocavernosus muscle and labial fat graft, a gracilis muscle or myocutaneous graft, omental pedicle grafts, and peritoneal flaps. Although there is no high-level evidence to support the use of these techniques, the interposed tissue has been presumed to help by creating an additional layer in the repair, to fill in “dead space” and reduce the risk of hematoma formation beneath the repair, to bring in a new blood supply into the area, and to reduce scarring. For each of these hypotheses, interpositional grafts might be considered to have their greatest benefit in the repair of radiation-associated fistulae.

At abdominal repair of vesicovaginal or rectovaginal fistulae, the use of a pedicled omental graft has been widely advocated (Kiricuta and Goldstein, 1972; Turner-Warwick, 1976). The omentum is dissected from the greater curve of the stomach and rotated down into the pelvis on either the right or left gastroepiploic artery; this technique may be used for any transperitoneal procedure but has its greatest potential advantage in radiation-associated fistulae.

The role of interpositional flaps in transabdominal repair procedures was reviewed by Evans and colleagues (2001). They reported 37 patients with fistulae of largely surgical cause, of whom 12 of 12 treated with an omental or peritoneal interpositional flap were cured, compared with 16 of 25 managed without interposition (64%); this finding was consistent for fistulae of both benign and malignant etiology. Although their cases were not randomized and the authors acknowledge that their overall cure rate (75%) was rather lower than in many series, nevertheless they concluded that an interpositional flap should be recommended when a transabdominal repair is undertaken, particularly when the repair is performed by a less experienced surgeon.

Although the Martius graft was widely employed in the context of obstetric fistula repair in the past, there is no high-level evidence to support its use in this context, and there seems to be a general move away from it among obstetric fistula surgeons. One small nonrandomized cohort study reported benefit in patients with multiple or recurrent fistulae, based on a univariate analysis (Rangnekar et al, 2000); another reported no advantage to the experienced obstetric fistula surgeon (Browning, 2006). In the series of fistulae of all causes from the United Kingdom reported by Hilton, the fistula closure rate was not significantly different between procedures in which an interpositional graft (omental or labial) was (92.0%) or was not (96.1%) used in the repair ($P = .264$; Fisher's exact test) (Hilton, 2012).

In the situation of vaginal repair of radiation-associated fistula, Pushkar and colleagues strongly advocated the use of the labial fat graft interposed at fistula repair (Pushkar et al, 2009). Hilton advocated its use to fill dead space in the lower vagina at complete colpocleisis (Hilton, 2011). With the former technique, closure at first operation was 48% (Pushkar et al, 2009); with the latter, 95% closure at first operation has been described (Hilton, 2012).

Labial skin grafts have also been employed in the repair of radiation-associated fistulae, either interpositional tissue or as a replacement for sloughed or indurated vaginal skin. Labia minora flaps with the outer surface de-epithelialized (Bizic et al, 2010) and labia majora flaps (Lai and Chang, 1999; Stanojevic et al, 2010) have both been described in this context.

Muscle and myocutaneous grafts have also been employed as interpositional tissue in fistula repair. These tend to be very bulky grafts and are perhaps best used, therefore, in circumstances of extreme tissue loss. The technique of rectus abdominis flap interposition was described in one series of 10 patients, although none of these cases were radiotherapy related (Tran et al, 1999). Viennas and colleagues reported one case of a radiation-induced VVF repair by this technique (Viennas et al, 1995). Gracilis muscle along with selective use of a buccal mucosal overlay graft has been used in rectourethral fistulae, with 84% cure in radiation-associated cases (Vanni et al, 2010).

Bladder Diverticula

BLADDER DIVERTICULA

The term *bladder diverticulum* is usually reserved for the finding of a subjectively large herniation of the bladder urothelium through the muscularis propria of the bladder wall. This results in a thin-walled, urine-filled structure adjacent to and connecting with the bladder lumen through a variably sized neck, or ostium. Histologically the diverticulum wall is composed of mucosa, subepithelial connective tissue or lamina propria, some scattered thin muscle fibers, and an adventitial layer (Fig. 90-1) (Peterson et al, 1973; Gil-Vernet, 1998). A fibrous capsule or pseudocapsule outer shell is often present and may be a useful surgical plane for excision (see later discussion). The outside wall of the bladder diverticulum often contains some residual scattered strands or bundles of smooth muscle; however, these are disorganized and nonfunctional. Therefore bladder diverticula generally empty poorly during micturition, leaving a large postvoid residual urine volume that results in the characteristic findings on presentation and imaging.

Classification, Pathophysiology, and Etiology

Bladder diverticula may occur in both adults and children but overall approximately 90% of bladder diverticula occur in adults (Psutka and Cendron, 2013). In addition, these lesions are far more common in males than females, with a ratio of approximately 9:1 in both the adult and pediatric age groups (Idrees et al, 2013).

Bladder diverticula may be classified as either congenital or acquired. Pathophysiology, presentation, clinical implications, and imaging may differentiate these two types. Congenital diverticula usually present during childhood, with a peak incidence in those less than 10 years old (Boechat and Lebowitz, 1978). These are usually solitary, occur most commonly in males (Stage and Tank, 1992; Sarihan and Abes, 1998; Evangelidis et al, 2005; Garat et al, 2007; Idrees et al, 2013), and are located lateral and posterior to the ureteral orifice, often in association with vesicoureteral reflux (Evangelidis et al, 2005; Garat et al, 2007; Psutka and Cendron, 2013). In contrast to adults, in whom coexistent lower urinary tract neurogenic dysfunction or obstruction is almost always present, the primary causation in the pediatric age group is generally thought to be a congenital weakness of the detrusor muscle, most often at the level of the ureterovesical junction with or without coexistent lower urinary tract abnormalities (Johnston, 1960; Hutch, 1961; Hutch et al, 1961; Stephens, 1979; Psutka and Cendron, 2013). Approximately 90% of pediatric or congenital bladder diverticula occur in the vicinity of the ureterovesical junction (Psutka and Cendron, 2013). Congenital bladder diverticula may occur in the presence of normal voiding dynamics in the absence of bladder outlet obstruction (Cendron and Alain, 1972; Barrett et al, 1976; Blane et al, 1994); however, up to 60% of congenital bladder diverticula may be associated with an underlying syndrome, neuropathic voiding dysfunction, or outlet obstruction

Female Urethral Diverticula

(Blane et al, 1994). Blane and colleagues (1994) reported the incidence of bladder diverticula in children to be approximately 1.7% in a pediatric genitourinary database of more than 5000 cases. Congenital bladder diverticula are usually relatively larger in comparison with those associated with obstruction or neurogenic bladder dysfunction (Gearhart, 2002).

The most common presentation of congenital bladder diverticula is acute urinary tract infection (UTI) resulting from stasis (Bauer and Retik, 1974; Pieretti and Pieretti-Vanmarcke, 1999; Evangelidis et al, 2005; Garat et al, 2007). Less common presentations include enuresis, pyelonephritis, acute retention, and stones. Notably, secondary bladder outlet obstruction may occur when the diverticulum extends distally toward the bladder neck (Taylor et al, 1979; Epstein et al, 1982; Verghese and Belman, 1984; Oge et al, 2002). Typically, congenital bladder diverticula are found in smooth-walled bladders and are not associated with significant trabeculation on cystoscopic examination (Hutch, 1961). In patients with prune-belly syndrome or posterior urethral valves, bladder diverticula may be located at the dome and be associated with aberrant voiding dynamics and/or anatomy. These are to be distinguished from the urachal diverticula seen in some pediatric urologic conditions. Importantly, unlike secondary or adult bladder diverticula, there is virtually no increased association with malignancy in congenital diverticula (Tamas et al, 2009; Alexander et al, 2012; Idrees et al, 2013).

Congenital bladder diverticula have been noted in association with a number of congenital syndromes, including Menkes syndrome (kinky hair or copper deficiency syndrome) (Harcke et al, 1977; Daly and Rabinovitch, 1981), Williams syndrome (Babbitt et al, 1979; Blane et al, 1994; Schulman et al, 1996), Ehlers-Danlos syndrome (Breivik et al, 1985; Levard et al, 1989; Schippers and Dittler, 1989; Rabin et al, 1991; Bade et al, 1994; Cuckow et al, 1994; Burrows et al, 1998), and fetal alcohol syndrome (Lewis and Woods, 1994). Whether there is a genetic predisposition to the formation of bladder diverticula in individuals without congenital syndromes is unclear, although congenital bladder diverticula have been reported in twins (Beall and Berger, 1978) and possibly as an autosomal dominant trait in a family (Hofmann et al, 1984). Because of the association of congenital bladder diverticula with genetic syndromes, it has been suggested that chromosomal testing should be pursued in such patients (Blane et al, 1994); however, this testing is generally not recommended in children with a single simple lesion (Psutka and Cendron, 2013).

Acquired (also termed "secondary") diverticula occur most commonly in the setting of bladder outlet obstruction or neurogenic vesicourethral dysfunction. Similar to the congenital type, these diverticula are located most commonly at the ureterovesical hiatus (Van Arsdalen and Wein, 1992) but also occur elsewhere in the bladder. Acquired diverticula in males usually occur after age 60, which corresponds to the age of the development of prostatic enlargement (Fig. 90-2). Bladder outlet obstruction (including that

Figure 90-1. Drawing of bladder diverticulum. A, Posterior view. B, Lateral view.

resulting from benign and malignant disease of the prostate), bladder neck obstruction (bladder neck hypertrophy, bladder neck contracture, etc.), and urethral stricture are commonly associated factors in adults, although obstruction is not considered to be present in all cases (Blacklock et al, 1983). Approximately 70% of bladder diverticula are associated with benign prostatic hyperplasia (Gerridzen and Futter, 1982). Historically, the reported prevalence of moderate- to large-sized bladder diverticula in association with “prostatism” is approximately 1% to 6% (Burns, 1944). Acquired diverticula are often multiple, typically found in association with significant bladder trabeculation (Wesselhoef et al, 1963), and much more common in males than females (Senger et al, 1952; Pool and Hacker, 1966). Bladder diverticula in females are relatively uncommon and often associated with bladder outlet obstruction (Gillon et al, 1988). When found in the female, careful evaluation of the bladder outlet will often reveal a cause for obstruction such as dysfunctional voiding, vaginal prolapse, bladder neck hypertrophy, urethral stricture, or iatrogenic obstruction resulting from anti-incontinence surgery (Safir et al, 1998) (Fig. 90-3). It is important to note that acquired bladder diverticula may also be found in children and young adults secondary to a number of conditions, including bladder neck dysfunction, posterior urethral valves, and neurogenic vesicourethral dysfunction. If the diverticu-

lum is located superolateral to the ureteral orifice, without involving the trigone in the setting of a neuropathic bladder and vesicoureteral reflux, it is termed a “Hutch” diverticulum, named after the individual who described this finding in a series of paraplegic individuals (Hutch, 1952). These diverticula may also occur in the setting of dysfunctional voiding.

Bladder diverticula may also be iatrogenic (Hernández et al, 1997; Suzuki et al, 2002; Chertin and Prat, 2008). Inadequate closure of the muscular layers of the bladder wall following a cystotomy for any indication may result in formation of a bladder diverticulum at a weak point of the suture line. “Iatrogenic” bladder diverticula may also occur following ureteral reimplantation surgery at the ureteroneocystostomy site (Ahmed and Tan, 1982; Sheu et al, 1998).

Diagnosis

Presentation and Evaluation

Acquired bladder diverticula do not typically produce specific symptoms and are most often found incidentally in the evaluation of other signs and symptoms, especially UTI. Because large bladder diverticula empty poorly or incompletely during voiding, symptoms and signs, if present, are usually attributed to urinary stasis within the diverticulum or, alternatively, to its mass effect in the lower abdomen and pelvis. Retrospectively, when queried, patient symptoms such as incomplete bladder emptying, lower abdominal fullness, and double voiding may be attributed to some large bladder diverticula. These symptoms, however, are nonspecific and can be due to prostatic enlargement, obstruction, or a number of other lower urinary tract conditions. Most bladder diverticula are found during the investigation of nonspecific lower urinary symptoms, hematuria, or infection—or, alternatively, noted incidentally during radiographic or endoscopic investigation of these conditions. As noted previously, congenital bladder diverticula most often present with UTI (Bauer and Retik, 1974; Pieretti and Pieretti-Vanmarcke, 1999; Evangelidis et al, 2005; Garat et al, 2007), but hematuria, abdominal pain, or an abdominal mass may be present as well. Inguinal hernias containing bladder diverticula have also been reported (Scardino and Upson, 1953; Bolton and Joyce, 1994; Buchholz et al, 1998; Schewe et al, 2000).

UTI in the male has been associated with bladder diverticula, because it is often an infection in a male that provides the impetus for further clinical investigation uncovering a diverticulum. A bladder diverticulum and subsequent urinary stasis may result in a predisposition for UTI and may also confer an increased difficulty in eradicating an existing infection (Shah, 1979; Taylor et al, 1979).

The initial evaluation of a bladder diverticulum includes a thorough history and physical examination, including digital rectal examination. In the male, prostate-specific antigen testing is pursued where appropriate. The history should quantitate lower urinary tract symptoms, query potential occult sources of neurogenic vesicourethral dysfunction (spinal surgery, etc.), and properly characterize any prior lower urinary tract surgery.

Urine analysis and urine culture as well as urine cytology should be considered in most patients with bladder diverticula, especially when nonoperative management is being considered. Abnormalities of the urine sediment are common in patients with bladder diverticula. Pyuria and hematuria are often present. In fact, relapsing or persistent pyuria unresponsive to antibiotic therapy may be an indication for bladder diverticulectomy in an otherwise asymptomatic patient. The finding of a bladder diverticulum in an adult should prompt further evaluation for bladder outlet obstruction, as well as endoscopic examination and imaging of the lower and upper urinary tract.

Imaging

The diagnosis of bladder diverticula relies on radiographic and endoscopic findings. Bladder diverticula are part of the radiologic

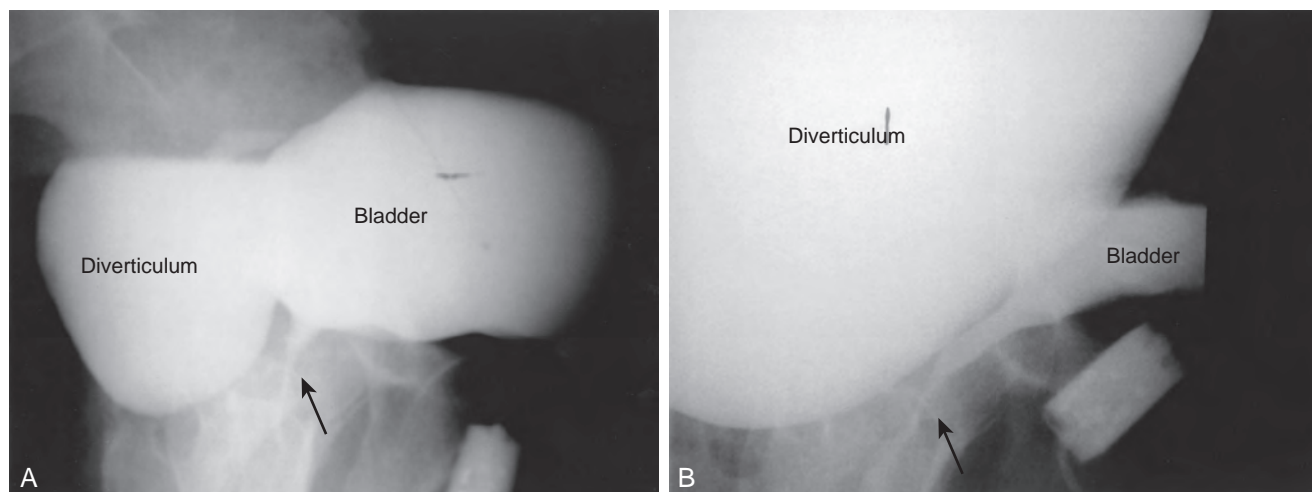

Figure 90-2. Voiding cystourethrogram (VCUG) demonstrating a bladder diverticulum in a male. **A**, The diverticulum is seen posterior to the bladder on this lateral voiding image (arrow points to urethra). There is a fluid-fluid level within the diverticulum representing the relatively denser contrast media settling below the urine. **B**, Later image from the VCUG demonstrates near emptying of the bladder with enlargement of the diverticulum.

continuum that includes cellules and saccules. Cellules, saccules, and bladder diverticula are thought to represent increasingly larger and therefore more severe manifestations of the same pathologic process involving elevated intravesical voiding pressure (Talner et al, 2000). Cellules and saccules represent small outpouchings between hypertrophied bands of bladder muscle, with saccules generally being larger than cellules. However, there are no universally agreed upon minimum size requirements that distinguish cellules, saccules, and bladder diverticula, and the differentiation among these three entities is often subjective and arbitrary (Talner et al, 2000).

As noted previously, bladder diverticula are often found incidentally in the radiographic investigation of recurrent UTIs or other nonspecific lower urinary tract symptoms or signs. The differential diagnosis of a fluid-filled structure adjacent to the bladder is lengthy and includes müllerian cysts; uterine, ovarian, and fallopian tube abnormalities; urachal cysts; ectopic ureter or ureterocele; and post-surgical changes, including lymphocele.

Fluoroscopically monitored voiding cystourethrography (VCUG) is an excellent study to detect bladder diverticula; however, false negatives are possible (Hernanz-Schulman and Lebowitz, 1985). A

VCUG with anterior-posterior, oblique, and lateral images provides information regarding anatomy, location, and size and also associated vesicoureteral reflux and, importantly, emptying of the bladder diverticulum with voiding. Vesicoureteral reflux may be found in up to 13% of patients with congenital bladder diverticula (Barrett et al, 1976). The finding of vesicoureteral reflux associated with bladder diverticula in the pediatric population has historically prompted ureteroneocystostomy in all cases; however, recently authors have pursued a more selective approach, reimplanting only those ureters associated with complicating factors such as renal scarring or progressive renal function deterioration (Afshar et al, 2005). Anomalous voiding into the diverticulum during a detrusor contraction may result in paradoxical enlargement of the bladder diverticulum during micturition (Wesselhoft et al, 1963) (see Fig. 90-2). Presumably, this occurs during the detrusor contraction as the contrast flows from an area of relatively high pressure in the bladder into the diverticulum, which represents an area of low pressure. In some instances the bladder may empty partly into the diverticulum and partly through the urethra. Often, with continued observation under fluoroscopy following the cessation of voiding, the empty bladder will start to refill as the

diverticulum discharges back into the bladder. The amount of post-void residual urine in the bladder diverticulum and bladder should be noted.

Cross-sectional imaging of the lower urinary tract may provide useful information regarding bladder diverticula and critical information regarding the surrounding anatomy. **Review of the radiographic films should accurately characterize the number, anatomy, and location of the diverticula as well as assess for masses within the diverticulum.** Filling defects within the diverticula or other bladder abnormalities should prompt further investigation (Fig. 90-4). If the neck of the diverticulum is obstructed from a tumor or otherwise not patent, cross-sectional imaging may be required for diagnosis (Dondalski et al, 1993). Finally, cross-sectional imaging will provide surgically relevant information, including the location of the ureters and surrounding structures (rectum, etc.), which can be quite distorted owing to the space-occupying nature of some large bladder diverticula.

Imaging of the upper urinary tract may include intravenous pyelography, ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI). **In the absence of hematuria or a known or suspected urinary tract malignancy, the goal of upper tract imaging in the adult is to evaluate for asymptomatic or silent hydroureteronephrosis related to the diverticulum** (Lebowitz et al, 1979; Sharma et al, 1997) which has been reported to be present in up to almost 7% of cases in one series (Fox et al, 1962). In children with bladder diverticula the reported incidence of upper tract abnormalities, including renal scarring, dysplasia, and hydronephrosis, has been reported to be as high as 30% (Tokunaka et al, 1980; Gotoh et al, 1987). Hydronephrosis may be related to obstruction of the ureter (Livne and Gonzales, 1985;

Kwan and Lowe, 1992), an underlying urodynamic abnormality that resulted in the formation of the diverticulum, vesicoureteral reflux in association with the diverticulum, and inflammation (Bellinger et al, 1985), or may be completely unrelated to the bladder diverticulum. A multichannel urodynamic study in combination with a VCUG or, alternatively, a video-urodynamic study is useful in this setting to differentiate upper from lower urinary tract causes of the hydronephrosis.

A bladder diverticulum may cause deviation with or without compression of the ipsilateral ureter. **Medial deviation of the pelvic ureter is most commonly seen; however, lateral deviation may also occur** (Talner et al, 2000) (Fig. 90-5). Such information is important in determining surgical approach and whether or not to place ureteric stents preoperatively. Furthermore, a bladder diverticulum that encompasses the ureteral orifice may create a functionally shortened intramural ureteral segment and result in vesicoureteric reflux (see later discussion).

Urodynamics

In the adult, bladder outlet obstruction and/or neurogenic voiding dysfunction may result in the formation of bladder diverticula. Therefore a video-urodynamic study can be very helpful in the investigation of these patients (Adot Zurbarano et al, 2005). The role of urodynamics in the evaluation of congenital bladder diverticula is less well defined (Psutka and Cendron, 2013). However, **failure to identify and treat an existing underlying urodynamic abnormality prior to or concomitantly with definitive surgical therapy for bladder diverticula may result in a high risk of recurrent diverticula or other problems following surgery.** Furthermore,

Figure 90-5. Bladder diverticulum with deviation of the ureter. This patient had a long history of recurrent urinary tract infections as a result of presumed prostatitis. **A**, Image from 10-minute intravenous urogram demonstrating medial deviation of the pelvic ureter (arrow). **B**, Voiding image from the voiding cystourethrogram revealed a large, smooth-walled bladder diverticulum (**D**) emanating from the trabeculated bladder (**B**).

successful treatment of the urodynamic abnormality may improve bladder emptying and potentially result in resolution of the symptoms and/or complications without the need for bladder diverticulectomy.

Bladder outlet obstruction, impaired contractility, elevated post-void residual urine, and detrusor overactivity are some of the urodynamic findings associated with bladder diverticula. Importantly, **bladder contractility may appear to be diminished on urodynamics because of the “pressure sink” effect of the bladder diverticulum.** This artifact occurs as the detrusor contracts and the intravesical contents are decompressed through the path of least resistance into the bladder diverticulum as opposed to the urethra (Wilson and Klufio, 1985). Nevertheless, when carefully measured, bladder contractility is not significantly different from that in individuals with benign prostatic hyperplasia without bladder diverticula (Adot Zurbano et al, 2005). In addition, elevated postvoid residual urine may be present as a result of retained urine in the diverticulum regardless of the presence or absence of impaired bladder contractility or bladder outlet obstruction.

Endoscopic Examination

Endoscopically, the entire interior of each bladder diverticulum should be thoroughly inspected for stones or abnormal-appearing epithelium. Flexible cystoscopy is often required to examine the entire interior of some diverticula. The location of the diverticula relative to the ureters and bladder outlet is noted, and the size of each diverticulum is carefully recorded (Fig. 90-6). Ideally, urine cytology should be obtained from the diverticulum during endoscopic examination. Any abnormal-appearing epithelium or lesions within the diverticulum are carefully biopsied. Extreme care must be taken during the biopsy to prevent perforation, because the wall of the diverticulum is very thin owing to the lack of a muscularis propria layer. All epithelial lesions under

consideration for biopsy should be considered malignant until proven otherwise. Perforation of the diverticular wall during biopsy risks tumor seeding into the perivesical fat with potential adverse prognostic implications.

Patients who elect nonoperative management of bladder diverticula are usually followed closely with periodic endoscopic examinations and cytology. The natural history of untreated bladder diverticula is unknown, but the possibility of malignant transformation over time because of urinary stasis within the diverticulum should be considered.

Associated Conditions

Bladder Outlet Obstruction

Acquired bladder diverticula are commonly found to exist in the setting of bladder outlet obstruction. Common causes of bladder outlet obstruction in the male include benign and malignant disease of the prostate and urethral stricture disease. Less common causes include bladder neck hypertrophy (primary bladder neck obstruction), vesicourethral anastomotic stricture following prostatectomy, and functional obstruction as a result of neurogenic vesicourethral dysfunction (bladder neck and/or striated sphincter dyssynergia). Strong consideration should be given toward management of bladder outlet obstruction prior to or concomitant with treatment of the bladder diverticulum. Whether such procedures should be done concomitantly or staged is controversial (Powell and Kreder, 2009). In some patients, especially those with small diverticula, treatment of bladder outlet obstruction alone may subsequently allow low pressure and complete emptying of the bladder diverticulum with micturition, thus reducing the potential for complications associated with these lesions and possibly avoiding the need for future operative intervention in the form of surgical diverticulectomy.

Figure 90-6. Endoscopic views of bladder diverticula. **A**, Lateral wall diverticulum in a male with bladder outlet obstruction. **B**, Paraureteral diverticulum in an adult female with vesicoureteral reflux and urinary tract infections. The right ureter is intubated with a catheter.

Malignancy

Much has been written about the association of bladder diverticula and malignancy. Historically, the risk of malignancy in bladder diverticula has been reported to be elevated. This increased risk of bladder cancer in diverticula has been attributed to urinary stasis and to chronic inflammation that is often found on pathologic examination of bladder diverticulum tissue (Kelalis and McLean, 1967; Idrees et al, 2013). Forty-five percent to 80% of bladder diverticulectomy specimens will harbor inflammatory changes to the urothelium (Gerridzen and Futter, 1982; Idrees et al, 2013). The overall prevalence of malignant tumors within a bladder diverticulum has been reported as ranging from 0.8% to 10% (Montague and Boltuch, 1976; Mičić and Ilić, 1983; Melekos et al, 1987; Baniel and Vishna, 1997; Golijanin et al, 2003). However, it is likely that the prevalence of bladder diverticula overall is under-reported and, as such, the prevalence of tumors within diverticula is probably considerably smaller than that noted here. Nevertheless, the most common histologic type of malignancy seen within bladder diverticula is transitional cell carcinoma in approximately 70% to 80% of cases, followed by squamous cell carcinoma in 20% to 25% of cases (Montague and Boltuch, 1976; Redman et al, 1976; Mičić and Ilić, 1983; Van Arsdalen and Wein, 1992; Yu et al, 1993; Baniel and Vishna, 1997; Golijanin et al, 2003). Tumors in bladder diverticula occur almost exclusively in adults, with a peak occurrence between ages 65 and 75 (Ostroff et al, 1973).

In addition to the potentially increased risk of bladder cancer, the finding of a neoplasm within a bladder diverticulum has particularly important diagnostic and therapeutic considerations because the bladder diverticulum wall lacks a well-developed muscularis propria layer. Therefore such a finding may portend a poorer prognosis because of the potential for rapid transmural involvement of invasive bladder cancer and extravesical extension. In addition, the lack of a defined muscular wall risks early dissemination of tumor cells into an extravesical location during transurethral resection of these lesions and makes precise pathologic staging difficult (Idrees et al, 2013).

The prognosis for patients with these tumors has been historically reported as poor (Faysal and Freiha, 1981; Mičić and Ilić, 1983; Das and Amar, 1986; Melekos et al, 1987), although some reports may suggest otherwise in selected patients (Montague and Boltuch, 1976; Baniel and Vishna, 1997). The poor prognosis has been attributed to delayed diagnosis and advanced stage at presentation

(Ostroff et al, 1973; Fellows, 1978; Faysal and Freiha, 1981; Mičić and Ilić, 1983). Historically, this has supported the prophylactic surgical treatment of all bladder diverticula, including asymptomatic and minimally symptomatic lesions (Kelalis and McLean, 1967). However, more recently it has been suggested that such management is not warranted, and observation with careful follow-up and periodic endoscopic surveillance is acceptable in asymptomatic individuals without evidence of dysplastic or malignant changes (Fellows, 1978).

Accurate identification of tumors within bladder diverticula has been demonstrated using a variety of radiographic techniques, including CT, MRI, and ultrasonography (Dragsted and Nilsson, 1985; Saez et al, 1985; Williams and Gooding, 1985; Lowe et al, 1989; Dondalski et al, 1993; Durfee et al, 1997; Mallampati and Siegelman, 2004) (see Fig. 90-4). Whether these modalities can reliably predict extravesical invasion and therefore affect staging and prognosis is not clear. It has been suggested that clinical stage at presentation is the most important prognostic factor for patients with tumors in bladder diverticula, with 5-year actuarial survival ranging from 83% \pm 9% in patients with superficial disease to 45% \pm 14% in those presenting with extradiverticular disease (Golijanin et al, 2003). One small series suggests that aggressive individualized multimodal therapy in these patients, including surgery, chemotherapy, and radiation therapy, may improve prognosis (Garzotto et al, 1996). Because pathologic staging following transurethral resection is difficult and often inaccurate, some authors have suggested a very aggressive approach to these tumors. This surgical staging approach involves an open exploration and partial or radical cystectomy without a prior transurethral resection (Redman et al, 1976). Others have advocated a selective individualized approach, taking into account the clinical stage and pathologic grade of the tumor (Golijanin et al, 2003).

Low-grade, low-stage tumors may be successfully treated with diverticulectomy alone (Baniel and Vishna, 1997; Sulaiman et al, 1998); however, it is important to recognize that the ability to reliably predict stage and grade preoperatively is limited, and therefore this approach should be undertaken only with caution in select cases, with adequate counseling and follow-up.

The role for less invasive treatment strategies of low-grade bladder tumors found in bladder diverticula is not well defined. As noted earlier, the potential risk of perforation with transurethral resection is higher with these tumors because of the lack of a defined muscularis propria layer. However, whether these patients can be safely treated with biopsy and fulguration with or without

intravesical chemotherapy/immunotherapy and interval cystoscopic surveillance for low-grade tumors, is unclear.

Other Associated Conditions

The location of many bladder diverticula at the level of the ureterovesical junction may explain the high incidence of associated ipsilateral ureteral abnormalities. For a ureter found within a diverticulum, the lack of a muscular backing to the diverticulum results in a functionally shortened intramural tunnel (see Fig. 90-6B). A very high prevalence of ipsilateral vesicoureteral reflux has been noted in association with congenital bladder diverticula (Amar, 1972; Barrett et al, 1976). Other considerations in the evaluation and management of bladder diverticula include the potential development of stones within the diverticulum, ureteral obstruction (Lebowitz et al, 1979; Bellinger et al, 1985; Kwan and Lowe, 1992; Khan et al, 1994; Sharma et al, 1997), and even the potential for the rare but life-threatening complication of perforation and/or rupture of the bladder diverticulum (Mitchell and Hamilton, 1971; Keeler and Sant, 1990; Itoh and Kounami, 1994; Jorion and Michel, 1999).

KEY POINTS: BLADDER DIVERTICULA—DIAGNOSIS

- Bladder diverticula do not contain a defined functional muscularis propria layer and therefore larger ones generally empty poorly with micturition.
- In the adult, bladder diverticula are often associated with bladder outlet obstruction or neurogenic vesicourethral dysfunction.
- Many bladder diverticula are found in a paraureteric location.
- Bladder diverticula are most often diagnosed incidentally in the evaluation of nonspecific lower urinary tract symptoms or infection.
- Patients with bladder diverticula should be evaluated for bladder outlet obstruction, and, if this is present, it should be addressed in advance of or concomitantly with definitive treatment of the bladder diverticulum.
- Malignancy can occur within a bladder diverticulum, and consideration should be given to the possibility of early extravesical disease extension owing to the lack of a defined muscularis propria.

Management

In general, if the etiology of the bladder diverticulum is believed to be consistent with bladder outlet obstruction and there are no other complicating factors, definitive treatment of the bladder outlet is indicated prior to formal diverticulectomy. This approach allows reassessment of the diverticulum following relief of outlet obstruction and, if bladder emptying is satisfactory and symptoms resolve, then the diverticulum may not require surgical excision. However, simultaneous open bladder diverticulectomy/open prostatectomy as well as simultaneous bladder diverticulectomy/transurethral prostatectomy can be performed (Porpiglia et al, 2004). If treatment of the obstruction is pursued initially and results in satisfactory emptying of the diverticulum postoperatively, and complicating factors such as reflux, infection, malignancy, or stones are absent, then ongoing surveillance of the diverticulum may be all that is required. Emptying of the diverticulum following relief of outlet obstruction may be assessed on VCUG, video-urodynamics, or cross-sectional imaging such as ultrasound.

Management options in the treatment of bladder diverticula include observation, endoscopic management, and surgical excision; however, there are many factors to consider during the evaluation of these lesions prior to deciding on appropriate therapy (Fig. 90-7).

Observation and Nonsurgical Management

Adult patients with minimal symptoms and no complicating factors may opt for observation with surveillance. These patients should be counseled regarding the potentially increased risk of malignancy and the need for periodic reassessment as well as the unpredictable course and potentially aggressive nature of malignancy if subsequently found in this setting. They should also be counseled regarding the symptoms and signs that indicate progression, including increasing lower urinary tract symptoms, hematuria, and UTI. The optimal schedule and type of surveillance for those individuals choosing observation is not well defined but consists of a periodic reassessment of symptoms, urine studies (including cytology), and endoscopic examination of the lower urinary tract (Yu et al, 1993).

Patients who have poor bladder emptying following relief of obstruction and remain symptomatic, or those who are unable or unwilling to undergo surgical excision of the bladder diverticulum, may be effectively treated with clean intermittent catheterization (CIC) or an indwelling catheter. In this setting, and in the absence of future complicating factors, ongoing CIC and periodic surveillance of the bladder diverticulum may be acceptable.

Indications for bladder diverticulectomy in children are similar to those in adults. However, in children with multiple bladder diverticula associated with a chromosomal syndrome, observation and medical management are usually preferred because of the inherent connective tissue disorders found in these patients, which impair postoperative wound healing, increase perioperative surgical risk, and predispose to recurrence (Psutka and Cendron, 2013).

Indications for Intervention

Many patients with incidentally found congenital or acquired bladder diverticula are managed expectantly and with periodic surveillance. Bladder diverticula can vary tremendously in size and, in some instances, are larger than the bladder itself. The size of the diverticulum does not appear to correlate with symptoms or complications and therefore cannot be used as an absolute indication to proceed with surgery. Bladder diverticulectomy is indicated for the treatment of lower urinary tract symptoms related to the diverticulum that are not otherwise responsive to medical therapy, or for the major complications directly related to it: persistent symptoms, chronic relapsing UTI, stones within the diverticulum, carcinoma or premalignant change, and upper urinary tract deterioration as a result of obstruction or reflux. Symptoms or complications related to bladder diverticula are most often due to poor emptying of the diverticulum and urinary stasis. Therefore excision of the diverticula would be expected to improve emptying of the lower urinary tract, provided that the primary problem that resulted in the formation of the bladder diverticulum (i.e., obstruction) has been adequately addressed.

Excision of bladder diverticula is most commonly elective. The relative merits of surgical excision versus surveillance should be carefully considered and discussed with each patient individually. The patient should be in relatively good health and be a reasonable surgical risk prior to considering the procedure. Preoperative medical status should be assessed and reversible risk factors (nutritional, renal, cardiac, pulmonary, etc.) corrected and/or optimized. Preoperative UTI should be treated. Patients who are prohibitive surgical risks because of concurrent medical illness or other factors should not undergo surgical excision but may be candidates for CIC or endoscopic treatment.

Endoscopic Management

Endoscopic management of bladder diverticulum may be considered in patients who are aged or somewhat debilitated, those who are not good candidates for an open operative approach, or those undergoing transurethral resection of the prostate in whom there exists an associated poorly draining diverticulum (Orandi, 1977; Vitale and Woodside, 1979). Transurethral

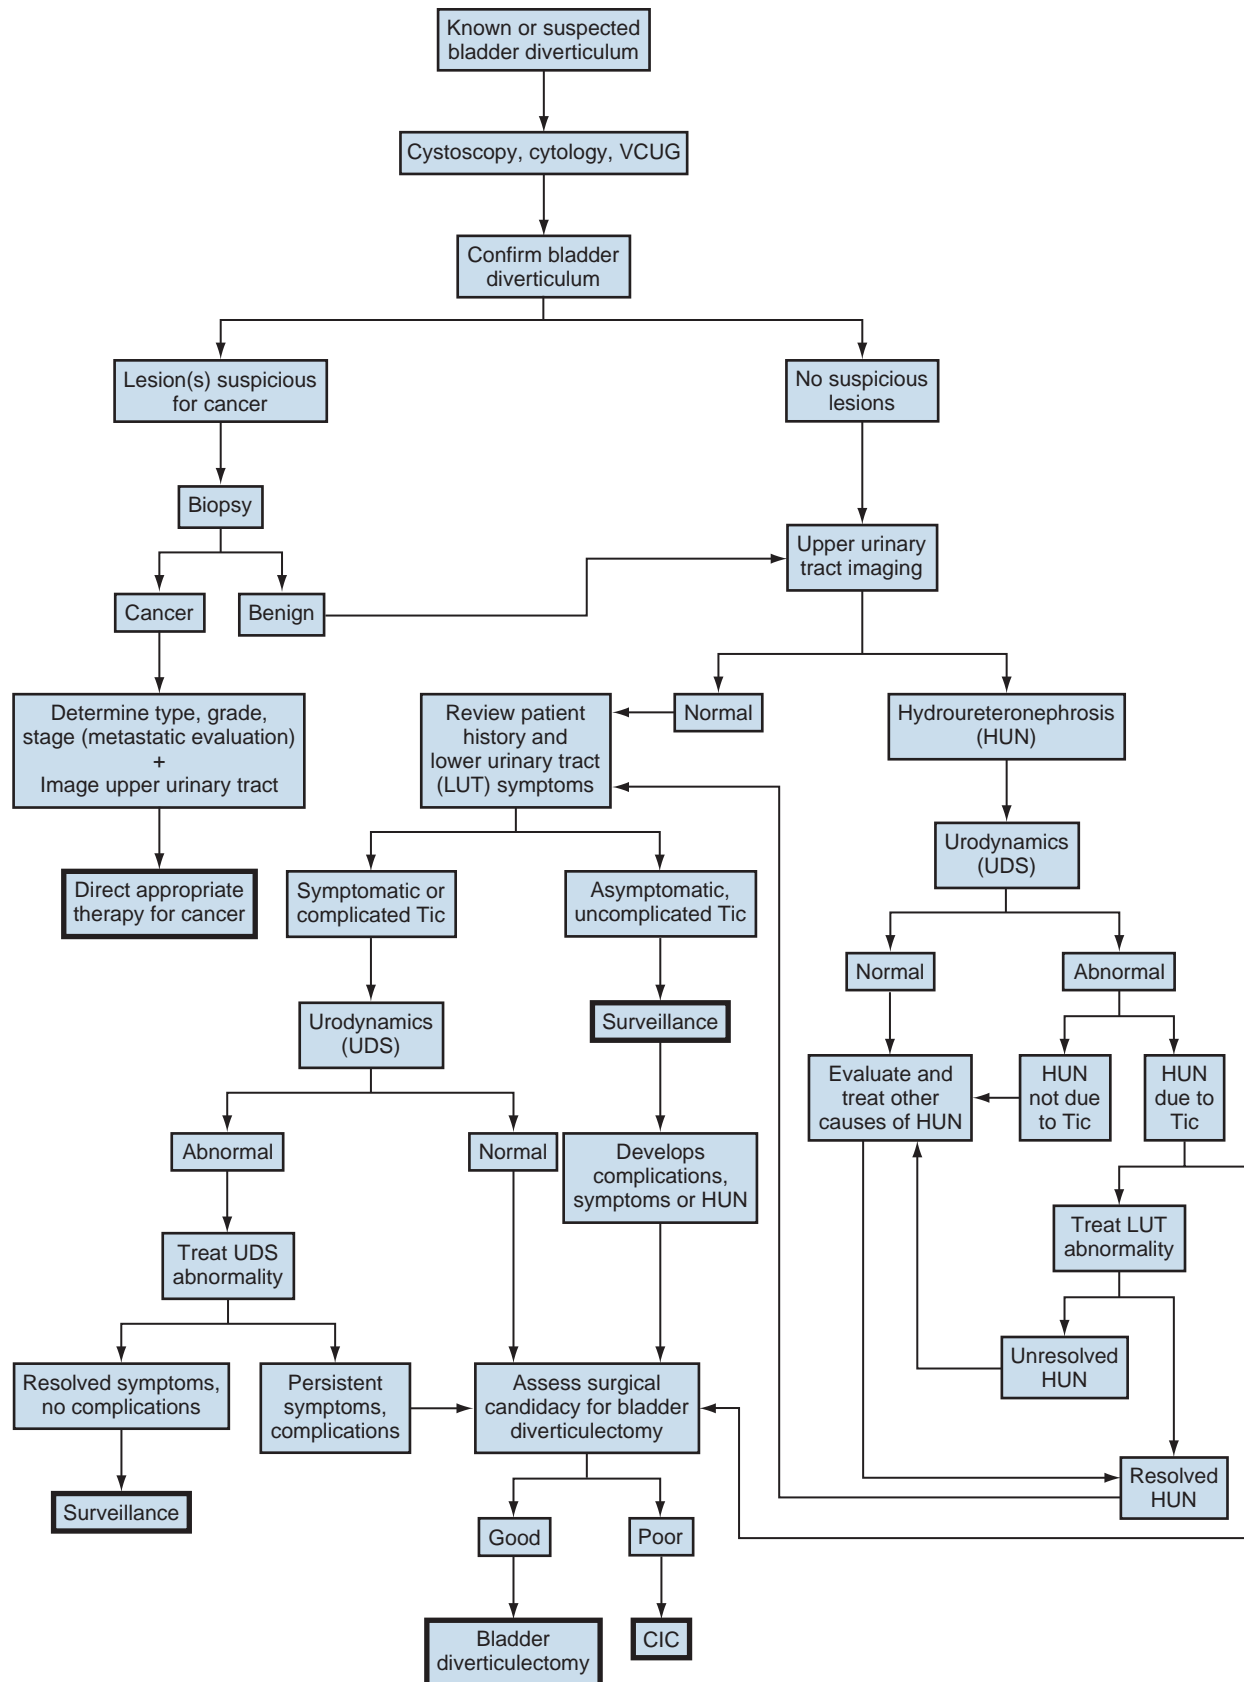

Figure 90-7. Algorithm for the evaluation and therapy of bladder diverticula. Bold-outlined boxes are potential endpoints in the algorithm. CIC, clean intermittent catheterization; Tic, bladder diverticulum; VCUG, voiding cystourethrogram. (Modified from Rovner ES, Wein AJ. Bladder diverticula in adults. resection of the diverticular neck has been reported to be successful in select cases (Vitale and Woodside, 1979). This technique is usually performed with a standard resectoscope. The neck of the diverticulum is incised using the resectoscope loop or Collins knife. Incisions are carried down to the muscular fibers of the bladder at the level of the ostium of the diverticulum. Circumferential resection of the entire neck may be performed. When successful, this procedure enlarges the neck of the diverticulum, disrupting the narrow sphincteric-like properties of its connection to the bladder lumen and thereby permitting improved emptying of the diverticulum during micturition. Although generally safe and well tolerated, this technique has resulted in urinary retention because of a reversal of flow during micturition and “venting” of the bladder contents into the diverticulum postoperatively (Schulze and Hald, 1983). This technique has been reported to be less successful in those individuals with large diverticula (Orandi, 1977; Vitale and Woodside, 1979). Transurethral resection of the diverticular neck may be combined with fulguration of the entire urothelial lining of the diverticulum (Clayman et al, 1984; Adachi et al, 1991a, 1991b; Yamaguchi et al, 1992). Fulguration of the lining of the diverticulum should result in obliteration of the diverticulum or a considerable reduction in its size.

Open Surgical Management

Open excision is usually performed through a transvesical approach, although extravesical and combined approaches have been described. In cases of marked prostatic enlargement and obstruction, open suprapubic prostatectomy and transvesical bladder diverticulectomy may be performed concomitantly. Adequate preoperative imaging and endoscopic evaluation should provide information regarding the size, number, and location of all bladder diverticula. Furthermore, the relationship of the adjacent anatomic structures, including the major pelvic vessels, ureters, and bowel, should be noted. Surgically, the bladder is most commonly approached extraperitoneally through a low midline or transverse incision. The retropubic space is entered and developed. Regardless of the technique used, careful dissection is required during excision of the diverticulum to avoid ureteral injury, because many bladder diverticula are located adjacent to the ureter or may be adherent to it. Ureteral stents are often placed preoperatively or intraoperatively to facilitate dissection and avoid ureteric injury. Often, several bladder diverticula are noted preoperatively. Simultaneous resection of all existing bladder diverticula should be performed to optimize postoperative bladder emptying (Gil-Vernet, 1998).

Transvesical Bladder Diverticulectomy. The transvesical approach to bladder diverticulectomy was first reported by Hugh Hampton Young in 1906 (Gil-Vernet, 1998). The bladder is opened along the anterior wall and suitable retraction is placed in order to visualize the neck of the diverticulum. For the excision of small diverticula, saccules, or cellules, a locking instrument such as an Allis-type clamp is passed through the neck of the diverticulum and the base or bottom of the diverticulum is grasped, pulled, and everted back into the bladder. In the absence of extravesical adhesions or inflammation, a small diverticulum can be completely everted into the bladder and exposed in this manner. The urothelium of the diverticulum at the level of the neck is incised circumferentially, and the diverticulum is removed. The defect in the bladder wall is closed with absorbable suture in two layers. Care must be taken when performing this technique to avoid injuring structures adherent or adjacent to the external surface of the diverticulum, because they may be blindly pulled into the bladder with the diverticulum wall and inadvertently injured during resection.

If eversion of the diverticulum is not possible because of adhesions or inflammation, or the diverticulum is too large to permit complete exposure during eversion, submucosal excision of the diverticulum may be performed. An anterior cystotomy is performed, the bladder is opened, and suitable retraction is placed to visualize the neck of the diverticulum within the bladder. The neck of the diverticulum is then identified and mobilized initially,

similar to the technique used for the first part of the dissection of the ureter during ureteroneocystostomy. The diverticular neck is circumscribed sharply with scissors or electrocautery, and the plane between the wall of the diverticulum and the surrounding fibrous capsule is defined (Fig. 90-8). Traction is placed on the edges of the neck of the diverticulum with Allis clamps (Scanlan International, St. Paul, MN) circumferentially, and the neck and then the exterior walls of the diverticulum are carefully mobilized from the surrounding tissues and delivered into the bladder lumen. Sharp and blunt dissection on the exterior wall of the diverticulum is performed in a well-defined periadventitial plane between the diverticulum wall and the fibrous pseudocapsule. Packing of the diverticulum with gauze may facilitate dissection and provide some countertraction (Fig. 90-9). The diverticulum is completely freed from its fibrous pseudocapsule and removed. The bladder wall defect is repaired in two layers with absorbable sutures. Drainage of the potential space left by the pseudocapsule is usually not necessary (Firstater and Farkas, 1977).

Combined Intravesical-Extravesical Approach. For individuals with large diverticula and/or considerable peridiverticular inflammation, a purely transvesical approach may not be feasible. In addition, involvement of the ureter within the diverticulum or severe peridiverticular inflammation encompassing the ureter may have altered the usual course of the ureter and may incur a prohibitive risk of injuring the ureter with a transvesical approach. Therefore a combined intravesical and extravesical approach may be warranted. Ureteral catheters are usually placed to prevent ureteral injury. The bladder is opened as if for a transvesical diverticulectomy. The diverticular neck is incised circumferentially. The surgeon's finger is then inserted into the diverticulum to identify the location of the rest of the diverticulum (Fig. 90-10). The diverticulum may be packed with gauze as well. If the neck of the diverticulum is sufficiently mobile, the anterior aspect of the neck is brought up into the operative field outside the bladder using the surgeon's finger. The overlying tissue is dissected free, and the anterior portion of the neck of the diverticulum is exposed and incised extravesically. The neck is circumferentially mobilized and then transected. The diverticular wall is then mobilized and dissected free of its attachments as described previously. In some cases, anterior reflection of the surgeon's finger allows opening of the diverticulum itself, and dissection can be carried out in the plane between the pseudocapsule and the urothelium in a completely extravesical fashion. In some cases, it may be necessary to divide the ipsilateral superior vesical pedicle to facilitate exposure and delivery of the diverticulum. If additional difficulty is encountered in exposing the diverticulum, the original cystotomy incision can be extended or enlarged in a “T” fashion over to the neck of the diverticulum. This procedure generally removes the entire diverticulum, including the mucosa and fibrous pseudocapsule. In cases in which considerable inflammation is encountered and the diverticulum is closely adhering to adjacent vital structures, it may be necessary to leave portions of the fibrous pseudocapsule in situ. The bladder is closed as described previously.

Laparoscopic and Robotic Diverticulectomy. Minimally invasive techniques, such as laparoscopy and robotics (Myer and Wagner, 2007), have been applied to surgical diverticulectomy (Das, 1992; Parra et al, 1992; Jarrett et al, 1995; Faramarzi-Roques et al, 2004; Abdel-Hakim et al, 2007; Macejko et al, 2008). As compared to open surgery the potential advantages of this approach include smaller incisions, less postoperative pain, shorter hospital stay, and a shorter convalescence. The principles of such minimally invasive techniques parallel those of the open surgical approach: (1) mobilization of the diverticular sac, including the neck; (2) excision of the sac; and (3) closure of the bladder. Transvesical as well as intra- and extraperitoneal approaches have been reported. The transvesical approach uses trocars inserted extraperitoneally directly into the bladder, thereby minimizing the risk to intraperitoneal contents (Pansadoro et al, 2009). Transperitoneal (Stolzenburg et al, 2011) and transvesical (Roslan et al, 2012) laparoendoscopic single-site surgery techniques have also been described that purport to even further minimize the risk to intra-abdominal structures.

Small nonrandomized, noncomparative case series suggest that outcomes using minimally invasive techniques, especially robotics, are similar to those with established open techniques (Eyraud et al, 2013). One small study compared laparoscopic versus open bladder diverticulectomy in 25 patients (Porpiglia et al, 2004). Outcomes

were similar, but notably blood loss and hospital stay were significantly lower in the laparoscopic group whereas operative time was almost twice as long (240 vs. 136 minutes). A review of 13 published series of robotic diverticulectomies involving a total of 44 patients revealed a mean operative time of 186 ± 68 minutes

(Eyraud et al, 2013). Potential advantages of the robotic approach as compared to the laparoscopic approach include improved surgical access and maneuverability in the deep pelvis as well as increased precision, dexterity, and visualization in complex reconstructive cases; however, this is somewhat counterbalanced by the increased cost of robotic equipment (Eyraud et al, 2013).

Complications

The most troubling potential complication during bladder diverticulectomy is ureteral injury. Fortunately, this is rare and can be avoided by careful attention to technique. Placement of a ureteral catheter perioperatively can be very helpful in identifying the ureter during surgery. If a ureteric injury is identified intraoperatively, a partial transection may be repaired primarily and stented. Complete transection usually mandates ureteral reimplantation into the bladder with or without a psoas hitch. Other complications include UTI, bleeding, prolonged urinary extravasation postoperatively, and urinary fistula. Vascular, bowel, or rectal injury may occur during bladder diverticulectomy owing to the proximity of these adjacent

structures to the diverticulum. Prompt recognition and repair are imperative. Good surgical technique, retraction, and maintenance of countertraction during extensive dissection will avoid many of these injuries. Fortunately rectal injuries are rare, though the location of many posterior bladder diverticula put the rectum at risk.

KEY POINTS: BLADDER DIVERTICULA—MANAGEMENT

- Bladder diverticulectomy is not indicated in all cases. Surgical treatment should be reserved for the treatment of symptoms related to the diverticulum, chronic relapsing UTI, stones within the diverticulum, carcinoma or premalignant change, and upper urinary tract deterioration as a result of obstruction or reflux.
- Surgical diverticulectomy can be performed with a variety of approaches, including minimally invasive techniques.

Combined intravesical-extravesical bladder diverticulectomy. **A,** The surgeon's finger is inserted into the diverticulum through a cystostomy, allowing identification of the diverticular neck. **B,** The diverticular neck is divided and the remaining portion of the diverticulum is dissected free from the surrounding tissues.

FEMALE URETHRAL DIVERTICULA

A urethral diverticulum (UD) in the female is a variably sized urine-filled periurethral cystic structure adjacent to the urethra within the confines of the pelvic fascia, connected to the urethra via an ostium. Such lesions represent some of the most challenging diagnostic and reconstructive problems in female urology. Urethral diverticula (UD) are notable for a bewildering array of clinical presentations ranging from completely asymptomatic, incidentally noted lesions on physical examination or imaging to very debilitating, painful vaginal masses associated with incontinence, stones, severe dyspareunia, and/or tumors. Anatomic variations between patients and in the location, size, and complexity of these lesions ensure that each case is unique.

Although described as early as the 19th century (Hey, 1805), the modern era of female UD began in the 1950s with the advent of positive-pressure urethrography (PPU) by Davis and Cian (1956). Over the next several years, there was a dramatic increase in number of cases of UD reported in the literature. A published series of 121 cases by Davis and TeLinde (1958) approximately doubled the number of cases reported during the previous 60 years. Development of adjuvant imaging techniques such as ultrasonography and

surface coil/endoluminal MRI have contributed greatly to further understanding of UD (Fig. 90-11).

Anatomy of the Female Urethra

The normal female urethra is a musculofascial tube approximately 3 to 4 cm in length, extending from the bladder neck to the external urethral meatus, suspended from the pelvic sidewall and pelvic fascia (tendinous arc of the obturator muscle) by a sheet of connective tissue known as the urethropelvic ligament. The urethropelvic ligament is composed of two layers of fused pelvic fascia that extend toward the pelvic sidewall bilaterally (Fig. 90-12). This structure can be considered to have an abdominal side (the endopelvic fascia) and a vaginal side (the periurethral fascia). Within and between these two leaves of fascia lie the urethra and the location of most UD.

The urethral lumen is lined by a urothelial layer proximally and a nonkeratinized stratified squamous cell type distally. The urethra may be conceptualized as a rich, vascular, spongy cylinder surrounded by an envelope consisting of smooth and skeletal muscle and fibroelastic tissue (Young et al, 1996). Within the thick, vascular lamina propria/submucosal layer are the periurethral glands (Fig. 90-13). These tubuloalveolar glands exist over the entire length of the urethra posterolaterally; however, they are most prominent over the distal two thirds, with the majority of the glands draining into the distal one third of the urethra. The Skene glands are the largest and most distal of these glands. These glands drain outside the urethral lumen, lateral to the urethral meatus. It is from pathologic processes involving the periurethral glands that most acquired female UD are thought to originate.

The urethra has several muscular layers: an internal longitudinal smooth muscle layer, an outer circular smooth muscle layer, and a skeletal muscle layer. The skeletal muscle component spans much of the length of the urethra but is more prominent in the middle third. It has a U-shaped configuration, being deficient dorsally. Ventral to the urethra, but separated from it by the periurethral fascia, lies the anterior vaginal wall (see Fig. 90-12). The location and competence of the urethral sphincters have important implications when considering surgical repair of UD because of the anatomic overlap of these two entities.

Arterial inflow to the urethra derives from two sources. The proximal urethra has a blood supply similar to the adjacent bladder, whereas the distal urethra derives its blood supply from the terminal branches of the inferior vesical artery through the vaginal artery that runs along the superior lateral aspect of the vagina (Hinman, 1993). Lymphatic drainage of the female urethra is to the external and internal iliac nodes from the proximal urethra, and to the superficial and deep inguinal lymph nodes from the distal urethra. Innervation to the female urethra is from the pudendal nerve (S2 to S4), and afferents from the urethra travel through the pelvic splanchnic nerves.

Urethral Diverticula

Pathophysiology and Etiology

As conceptualized by Young and colleagues (1996), UD represent a cavity dissecting within the confines of the fascia of the urethropelvic ligament. This defect is often an isolated cystlike appendage with a single discreet connection to the urethral lumen known as the neck, or ostium (Fig. 90-14). However, complicated anatomic patterns may exist, and in certain cases the UD may extend partially (saddlebag UD) around the urethra, anterior to the urethra (Vakili et al, 2003), or circumferentially around the entire urethra (Rovner and Wein, 2003) (Fig. 90-15).

The exact origin of UD is still unproven. A major debate in the early part of the 20th century focused on whether UD were congenital or acquired lesions (Johnson, 1938; Gilbert and Rivera Cintron, 1954; Pinkerton, 1963). Although this condition exists in children, the diagnosis may represent a different clinical entity from adult female UD. Scattered reports of congenital UD in female

infants have been described (Glassman et al, 1975). Marshall (1981) reported five cases of UD in young females, of whom three underwent spontaneous regression. Congenital anterior UD is a well-described entity in boys (Kirks and Grossman, 1981; Lau and Ong, 1981; Kaneti et al, 1984), but this is considered to be an

entirely different clinical entity from UD in the female. Congenital Skene gland cysts have been reported (Kimbrough and Vaughan, 1977; Lee and Kim, 1992) but are considered extremely rare. Diverticula in the pediatric population have been attributed to a number of congenital anomalies, including an ectopic ureter draining into a Gartner duct cyst and a forme fruste of urethral duplication (Silk and Lebowitz, 1969; Vanhoutte, 1970; Boyd and Raz, 1993). The vast majority of UD, however, are classified as acquired and are diagnosed in adult females. In two large series of UD, there were no patients reported who were younger than 10 years of age (Davis and TeLinde, 1958; Davis and Robinson, 1970), arguing against a congenital etiology for these lesions. Although it is possible that there exists a congenital defect in patients that results in or represents a precursor to UD, which then only becomes symptomatic later in life, it is still unproven.

There are multiple theories regarding the formation of acquired UD. For many years, acquired UD were believed to be most likely due to trauma from vaginal childbirth (McNally, 1935). It was postulated that mechanical trauma during vaginal delivery resulted in herniation of the urethral mucosa through the muscular layers of the urethra with the subsequent development of a UD. However, up to 20% to 30% of patients in some UD series are nulliparous (Lee, 1984; Ganabathi et al, 1994), which may significantly discount parity as a risk factor. Trauma with forceps delivery, however, has been reported to cause UD (Kłyszczko et al, 1985), and the radiographic appearance of periurethral injectable agents,

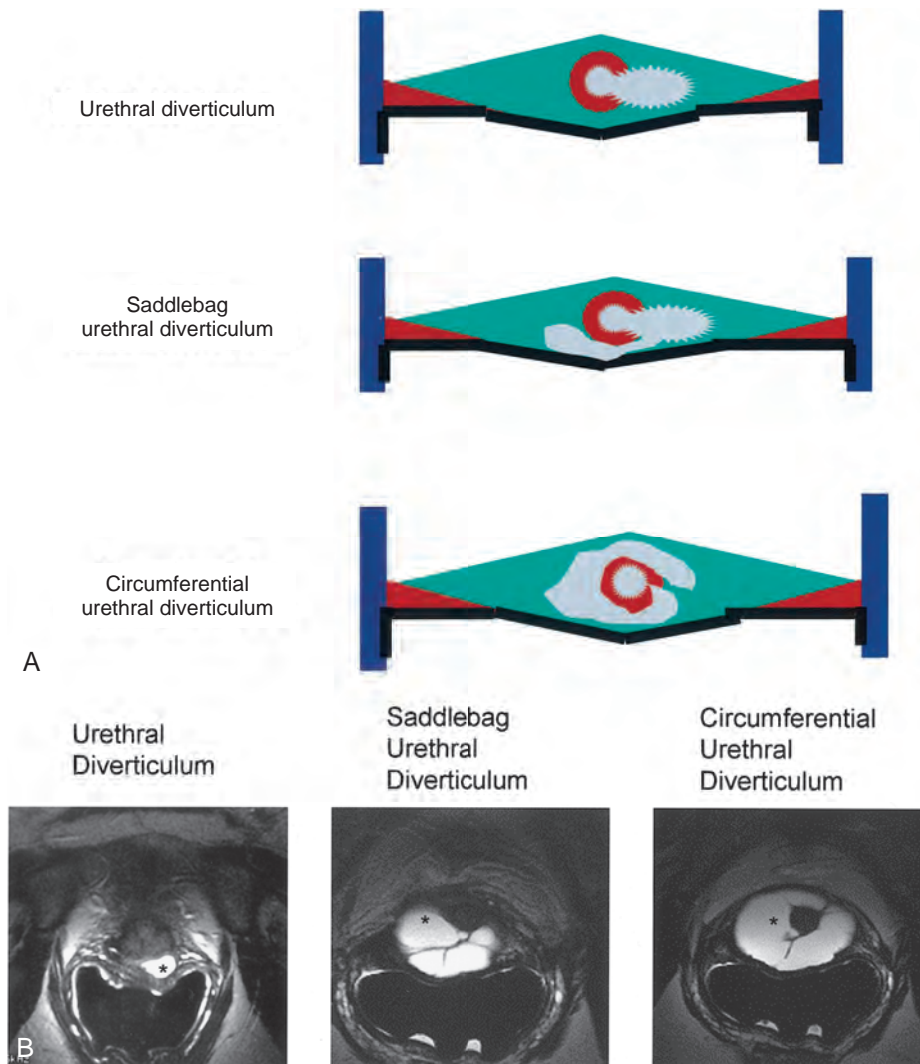

Figure 90-15. Multiple different morphologies of urethral diverticulum (UD) may exist. A, Schematic diagrams representing three different morphologies of UD. B, Endoluminal magnetic resonance images corresponding to each of the configurations in three different patients (asterisk indicates UD).

including collagen (Clemens and Bushman, 2001; Bridges et al, 2005) and other injectable agents (Castillo-Vico et al, 2007), can simulate a UD.

The periurethral glands are thought to be the probable site of origin of acquired UD (Young et al, 1996). Huffman's anatomic work with wax models of the female urethra was critical to the early theories regarding the pathophysiology of UD and the involvement of the periurethral glands (Huffman, 1948). By reviewing 10- μ m transverse sections, he refuted earlier anatomic descriptions of the glandular anatomy of the female. He characterized the periurethral glands as located primarily dorsolateral to the urethra, arborizing proximally along the urethra, and yet draining into ducts located in the distal one third of the urethra (see Fig. 90-13). Furthermore, he noted that periductal and interductal inflammation was found commonly. In support of these observations and an infectious (acquired) etiology of UD, in over 90% of UD cases the ostium is located posterolaterally in the mid- or distal urethra, which corresponds to the anatomic location of the periurethral glands (Lang and Davis, 1959; MacKinnon et al, 1959).

Although there are probably other unknown factors that may facilitate the initiation, formation, or propagation of UD, infection of the periurethral glands seems to be the most generally accepted common etiologic factor in most cases. Peters and

Vaughan (1976) found a strong association with concurrent or previous infection with *Neisseria gonorrhoeae* and UD. However, the initial infection and, especially, subsequent reinfections may originate from a variety of sources, including *Escherichia coli* and other coliform bacteria as well as vaginal flora. Nevertheless, UD have been attributed historically to recurrent infection of the periurethral glands, with obstruction, suburethral abscess formation, and subsequent rupture of these infected glands into the urethral lumen. Continual filling and pooling of urine in the resultant cavity may lead to stasis, recurrent infection, and eventual epithelialization of the cavity, forming a permanent UD. This concept was first popularized by Routh (1890) over a century ago and has now become the most widely accepted theory regarding the formation of female UD. Reinfection, inflammation, and recurrent obstruction of the neck of the cavity are theorized to result in patient symptoms and enlargement of the diverticulum. It should be noted that Daneshgari and colleagues (1999) have reported non-communicating UD diagnosed by MRI. Whether this lesion represents a forme fruste of UD or simply a UD with an obstructed ostium is unclear.

Young and colleagues (1996) have formulated a modern hypothesis regarding the pathogenesis of UD through extensive clinical experience with this entity, including the diagnosis, imaging, and

surgical repair of UD. These authors have proposed that acquired UD results from infection and obstruction of the periurethral glands. These glands are normally found in the submucosal layer of the spongy tissue of the distal two thirds of the urethra. Repeated infection and abscess formation in these obstructed glands eventually result in enlargement and expansion. Initially the expanding mass displaces the spongy tissue of the urethral wall and then enlarges to disrupt the muscular envelope of the urethra. This results in herniation into the periurethral fascia. The enlarging cavity can then expand and dissect within the leaves of the periurethral fascia and urethropelvic ligament. This expansion occurs most commonly ventrally, resulting in the classic anterior vaginal wall mass palpated on physical examination in some patients with UD. However, it is important to note that these may also expand laterally, or even dorsally, about the urethra. Eventually, the abscess cavity ruptures into the urethral lumen, resulting in the communication between the UD and the urethral lumen.

This proposed pathophysiology appears to adequately explain the anatomic location and configuration of many UD and is supported by the work of Huffman noted previously. However, it is not without critics. Some have argued that UD represent one form in the continuum of periurethral cysts (Tsivian et al, 2009). In addition, about one third of UD occur in the proximal portion of the urethra (Thomas et al, 2008), which is not consistent with the location of the majority of the drainage ducts for the periurethral glands. Finally, if this proposed pathophysiology were true, the finding of periurethral abscesses as a result of infection and enlargement of the periurethral glands should be at least as common as UD, but such lesions are indeed rarely seen clinically.

Prevalence

Moore (1952) stated that UD as an entity is “found in direct proportion to the avidity with which it is sought.” Although it is not considered a rare lesion today, less than 100 cases of UD had been reported in the literature prior to 1950. With the development of sophisticated imaging techniques, including PPU in the 1950s, the diagnosis of UD became increasingly common.

The true prevalence of female UD, however, is not known; it is reported to occur in up to 1% to 6% of adult females in some series. Determining the true prevalence of UD would require appropriate screening and imaging of a large number of symptomatic and asymptomatic adult female subjects in a primary care setting, which, to date, has not been done. Bruning (1959) found UD in 3 of 500 female autopsy specimens. In 1967, Andersen reported the results of PPU done for 300 women with cervical cancer but without lower urinary tract symptoms and found UD in 3%. Aldridge and colleagues (1978) reported a prevalence of UD of 1.4% in women presenting with incontinence and related symptoms. Stewart and associates (1981) found UD in 16 of 40 highly symptomatic females investigated with PPU. Endorectal coil MRI was performed on 140 consecutive female patients with lower urinary tract symptoms, and the incidence of UD was approximately 10% (Lorenzo et al, 2003). However, this represented a series of symptomatic females at a tertiary referral center and therefore probably is not reflective of the general population. Burrows and colleagues (2004) reviewed U.S. hospital and ambulatory surgery databases and concluded that the rate of urethral diverticulectomy surgery from 1994 to 1996 was approximately 6.7 per 1 million females. However, this is well below the historical prevalence figures cited previously. Further complicating an accurate assessment of the epidemiology of UD is that the condition can be asymptomatic and is often misdiagnosed or overlooked.

Some series have suggested a racial predilection, with African-Americans being as much as six times as likely to develop UD as their Caucasian counterparts (Davis and Robinson, 1970). This distribution was historically believed to be attributed to an urban bias because most of the clinical series of these cases were reported from academic medical centers in large cities. However, a recent retrospective series from the Cleveland Clinic revealed that approximately two thirds of urethral diverticulectomies performed at that

institution over a 26-year period were in Caucasians. Nevertheless, inpatient surgery for UD in the United States occurred threefold more commonly in African-Americans than in whites from 1979 to 1997 (Burrows et al, 2004).

Diverticular Anatomy and Histology

The interior surface of UD may be urothelial, squamous, columnar, or cuboidal epithelium, or mixed (Tsivian et al, 2009). In some cases, the epithelium is absent and the wall of the UD consists of only fibrous tissue. Two thirds of resected UD demonstrate inflammatory changes (Thomas et al, 2008).

Most UD demonstrate benign histopathology but premalignant and malignant changes can be seen. Approximately 10% of urethral diverticulectomy specimens may demonstrate significant histopathologic abnormalities, including metaplasia, dysplasia, or frank carcinoma, that require long-term follow-up or additional therapy (Thomas et al, 2008). Fewer than 100 cases of carcinoma within UD have been reported in the English-language literature (Rajan et al, 1993). The most common malignant pathology in UD is adenocarcinoma, followed by transitional cell and squamous cell carcinomas (Rajan et al, 1993; Thomas et al, 2008). This is in direct contrast to primary urethral carcinoma, in which the primary histologic type is squamous cell carcinoma. Some authors have suggested that UD is associated with the development of urethral adenocarcinoma in the female (Oliva and Young, 1996). If this is true, then observational management or nonexcisional therapy of UD, such as marsupialization or endoscopic incision, should always be combined with a biopsy to rule out malignancy (McLoughlin, 1975). There is no consensus on proper treatment in these cases, and recurrence rates are high with local treatment alone (Rajan et al, 1993). The incidental finding of malignancy in these cases can be particularly troubling when found intraoperatively, or even more disturbing on the postoperative pathology report. Although it is interesting to speculate, it has not been conclusively demonstrated that any particular preoperative imaging modality, such as ultrasonography or MRI (Chung et al, 2010), can reliably and prospectively diagnose a small malignancy arising in a UD. When considering curative therapy, it is unclear whether extensive surgery, including cystourethrectomy with or without adjuvant external beam radiotherapy, is superior to local excision followed by radiotherapy (Patanaphan et al, 1983).

Multiple benign lesions, including both nephrogenic adenoma and endometriosis, have been described within UD (Palagiri, 1978; Peterson and Matsumoto, 1978; Piazza et al, 1987; Paik and Lee, 1997). Pathologically, nephrogenic adenoma can be difficult to differentiate from adenocarcinoma.

Calculi within UD are not uncommon and may be diagnosed in 4% to 10% of cases (Ward et al, 1967; Ginesin et al, 1988; Romanzi et al, 2000) and are most likely due to urinary stasis and/or infection (Fig. 90-16). They may be suspected by physical examination findings or noted incidentally on imaging evaluation. The presence of a stone will not significantly alter the evaluation or surgical approach and can be considered an incidental finding. The stone is removed with the UD specimen at the time of surgery.

UD are found within the periurethral fascia bordered by the anterior vaginal wall ventrally. The size of the lesion may vary from only a few millimeters to several centimeters. In addition, the size may vary over time as a result of inflammation, intermittent obstruction of the ostium, and subsequent drainage into the urethral lumen. In the sagittal plane, UD are most often located and centered at the level of the middle third of the urethra, with the luminal connection, or ostium, located posterolaterally. They may extend distally along the vaginal wall almost to the urethral meatus, or proximally up to and beyond the bladder neck underneath the trigone of the bladder (Fig. 90-17). A bewildering array of configurations can be noted on imaging and at surgical exploration (Table 90-1). In the axial plane, the UD cavity may extend laterally along the urethral wall and, in some cases, around to the dorsal side of the urethra or may wrap circumferentially around the entire urethra.

Figure 90-16. Calculi within a urethral diverticulum. A, Scout film shows a calcified density overlying the symphysis pubis. B, Voiding image from a voiding cystourethrogram demonstrates that the density seen on the scout film represents a stone within a urethral diverticulum.

Figure 90-17. T2 MRI demonstrating a large urethral diverticulum (D) extending to the trigone of the bladder (B) in the sagittal (A) and coronal (B) planes. P, symphysis pubis; V, vagina.

UD may be bilobed (dumbbell shaped), extending across the midline in a so-called saddlebag configuration (see Fig. 90-15). Multiple loculations are not uncommon, and approximately 6% of patients have multiple UD at presentation (Thomas et al, 2008). Varying degrees of sphincteric compromise may exist because of the location of diverticulum relative to the proximal and distal urinary sphincter mechanisms, or sphincteric compromise may coexist with UD as a result of other factors. This is important to note when considering surgical repair, as discussed later.

Presentation

The majority of patients with UD present between the third and seventh decades of life (Johnson, 1938; Moore, 1952; Pathak and House, 1970; Ginsburg and Genadry, 1983; Ganabathi et al, 1994). The presenting symptoms and signs in patients with UD are protean (Box 90-1). The classic presentation of UD has been described

historically as the “three Ds”—dysuria, dyspareunia, and dribbling (postvoid)—but this presentation is only infrequently seen. Such a designation is of historical interest only because it was coined in the period before extensive radiologic imaging was available (Lee and Fynes, 2005). However, individually or collectively, these symptoms are neither sensitive nor specific for UD. Although presentation is highly variable, the most common symptoms are irritative (frequency, urgency, etc.) lower urinary tract symptoms, pain, and infection (Davis and TeLinde, 1958; Davis and Robinson, 1970; Peters and Vaughan, 1976; Leach et al, 1986). Dyspareunia will be noted by 12% to 24% of patients (Davis and TeLinde, 1958; Davis and Robinson, 1970). Approximately 5% to 32% of patients will complain of postvoid dribbling (Davis and Robinson, 1970; Ganabathi et al, 1994) and one third will have associated incontinence (Ganabathi et al, 1994). Recurrent cystitis or UTI is also a frequent presentation, seen in one third of subjects (Davis and Robinson, 1970; Ganabathi et al, 1994), probably as a

BOX 90-1 Signs and Symptoms of Urethral Diverticula**SYMPTOMS**

Vaginal or pelvic mass
 Pelvic pain
 Urethral pain
 Dysuria
 Urinary frequency
 Postvoid dribbling
 Dyspareunia
 Urinary urgency
 Incontinence
 Urinary hesitancy
 Vaginal or urethral discharge
 Double voiding
 Sense of incomplete emptying

SIGNS

Recurrent urinary tract infection
 Hematuria
 Vaginal or perineal tenderness
 Urinary retention
 Vaginal mass
 Urethral discharge with stripping of anterior vaginal wall

Figure 90-18. Large anterior vaginal wall mass. The urethral catheter (C) is seen superiorly, and a weighted vaginal speculum (S) is seen inferiorly. Scott retractor hooks are seen exposing the anterior vaginal wall in this intraoperative photograph.

result of urinary stasis in the UD. Multiple bouts of recurrent cystitis should alert the clinician to the possibility of a UD. Other complaints include pain, a vaginal mass, hematuria, vaginal discharge, obstructive symptoms or urinary retention, and incontinence (stress or urge). Patients may present with complaints of a tender or nontender anterior vaginal wall mass, which upon gentle compression may reveal retained urine or purulent discharge per the urethral meatus. Although spontaneous rupture of these lesions is extremely rare, urethrovaginal fistula may result under these circumstances (Nielsen et al, 1987). Notably, up to 20% of patients diagnosed with UD may be completely asymptomatic, having the lesions diagnosed incidentally on imaging or physical examination.

It is important to note that the size of the UD does not correlate with symptoms. In some cases, very large UD may result in minimal symptoms, and, conversely, some UD that are nonpalpable may result in considerable patient discomfort and distress. Finally, symptoms may wax and wane and even resolve for long periods of time. The reasons for these exacerbations and remissions are poorly understood but may be related to periodic and repeated episodes of infection and inflammation.

Because many of the symptoms associated with UD are nonspecific, patients may often be misdiagnosed and treated for years for a number of unrelated conditions before the diagnosis of UD is made. This may include therapies for interstitial cystitis, recurrent cystitis, vulvodynia, endometriosis, and vulvovestibulitis. In one series of 46 consecutively examined women eventually diagnosed with UD, the mean interval from onset of symptoms to diagnosis was 5.2 years (Romanzi et al, 2000). In this series, women consulted with an average of nine physicians prior to the definitive diagnosis being made, despite the fact that 52% of women had a palpable mass on examination. This underscores the importance of a baseline level of suspicion and a thorough pelvic examination in female patients complaining of lower urinary tract symptoms or other symptoms that may be associated with UD.

UD has also been reported to present during pregnancy. Moran and colleagues (1998) reported four cases of UD diagnosed during pregnancy. Conservative treatment included antibiotics and aspiration or incision and drainage. Two women delivered vaginally and the other two delivered by cesarean section for unrelated reasons.

In one patient, drainage was performed during labor to facilitate delivery. Three of the four women had definitive repair performed after delivery. It is not known if pregnancy is associated with formation of UD, although patients may be more likely to become symptomatic during this period. Usually, conservative management with antibiotics may be desirable until after delivery to avoid precipitating premature labor, although successful surgical treatment during pregnancy has been reported (Wittich, 1997).

Evaluation and Diagnosis

The diagnosis of UD can be made with a combination of a thorough history, physical examination, appropriate urine studies (including urine culture and analysis), endoscopic examination of the bladder and urethra, and selected radiologic imaging. A urodynamic study may also be helpful in completing the evaluation in selected cases.

History and Physical Examination. A thorough history is essential in patients presenting with a diagnosis of UD as well as those without an established diagnosis. Though the presenting symptoms and signs are nonspecific for UD, a thorough accounting of lower urinary tract symptoms, signs (hematuria, etc.), prior diagnostic studies, and response to therapy is critical. Such an approach will permit appropriate counseling regarding improvement or resolution of symptoms in those individuals with a diagnosis of UD and may suggest such a diagnosis in those presenting as diagnostic dilemmas. Important historical data include prior pelvic surgery, especially incontinence procedures; bulking agents may present as UD on imaging (Kumar et al, 2011) and prior sling surgery may present difficulties in accessing and surgically repairing the UD. The presence or absence of urinary incontinence and pad usage, as well as the type of incontinence (urge vs. stress vs. postvoid dribbling, etc.) should be recorded. Sexual function and dyspareunia should be documented as well because vaginal reconstructive surgery may have adverse (or favorable) effects on these individuals.

During physical examination, the anterior vaginal wall should be carefully palpated for masses and tenderness. The location, size, and consistency of any suspected UD should be recorded. Most UD are located ventrally over the middle and proximal portions of the urethra, corresponding to the area of the anterior vaginal wall 1 to 3 cm inside the introitus (Fig. 90-18). More distal lesions

near the urethral meatus or distorting the urethral meatus are likely Skene gland cysts or abscesses. Only about one third of UD present with a tender anterior vaginal wall mass (Ganabathi et al, 1994). However, UD may also be located anterior to the urethra or extend partially or completely around the urethral lumen. UD may also extend proximally toward the bladder neck. These UD may produce distortion of the bladder outlet and trigone of the bladder on cystoscopy or on radiographic imaging. Special care should be taken during surgical excision and reconstruction owing to concerns for intraoperative bladder and ureteral injury, as well as the potential development of postoperative voiding dysfunction and urinary incontinence.

Distal vaginal masses or perimeatal masses may represent other lesions, including abnormalities of Skene glands (see later discussion). The differentiation between these lesions sometimes cannot be made on the basis of a physical examination alone and may require additional radiologic imaging. A particularly hard anterior vaginal wall mass may indicate a calculus or malignancy within the UD and mandates further investigation. During physical examination, the urethra may be gently “stripped” or “milked” distally in an attempt to express purulent material or urine from within the UD cavity. Although often described for the evaluation of UD, this maneuver is not successful in producing the characteristic discharge per urethral meatus in the majority of patients (Leach and Bavendam, 1987).

The vaginal walls are assessed for atrophy, rugation, and elasticity. Poorly estrogenized, atrophic tissues are important to note if surgery is being considered for definitive treatment. These tissues are mobilized intraoperatively and may be used for flaps during excision and reconstruction. Topical estrogens may be administered preoperatively in such cases to improve the quality of the tissues. The distal vagina and vaginal introitus are also assessed for capacity. These factors may have an impact on surgical planning, because a narrow introitus can make surgical exposure difficult and may mandate an episiotomy or other measures. Finally, during physical examination a provocative maneuver to elicit stress incontinence should be performed, as well as an assessment of the presence or absence of any vaginal prolapse.

Urine Studies. Urine analysis and culture should be performed. The most common organism isolated in patients with UD is *E. coli*. However, other gram-negative enteric flora, as well as *N. gonorrhoeae*, *Chlamydia*, streptococci, and staphylococci, are often present (Davis and TeLinde, 1958; Hoffman and Adams, 1965). A sterile urine culture does not exclude infection, because these patients are often on antibiotic therapy at presentation. In patients with irritative symptoms or in whom a malignancy is suspected, urine cytology can be performed.

Cystourethroscopy. Cystourethroscopy is performed in an attempt to visualize the UD ostium as well as to evaluate for other causes for the patient’s lower urinary tract symptoms. A flexible fiberoptic cystoscope or specially designed rigid female cystoscope can be extremely helpful in evaluating the female urethra. The short beak of the female cystoscope and the lack of a beak on a flexible cystoscope maintain the discharge of the irrigation solution immediately adjacent to the lens and thus aid in distention of the relatively short (as compared to the male) urethra, permitting improved visualization. It may also be advantageous to compress the bladder neck while an assistant simultaneously applies pressure to the diverticular sac with a finger. Luminal discharge of purulent material can often be seen with this maneuver or with simple digital compression of the UD during urethroscopy. The UD ostium is most often located posterolaterally at the 4 and 8 o’clock positions at level of the mid-urethra but can be very difficult to identify in some patients (Fig. 90-19). The success in identifying a diverticular ostium on cystourethroscopy is highly variable and is reported to range from 15% to 89% (Davis and Robinson, 1970; Leach and Bavendam, 1987; Ganabathi et al, 1994). As a note of caution, patients with UD are often highly symptomatic, and endoscopic examination can be very difficult to initiate or complete without anesthesia. Notably, a positive examination may help in

Figure 90-19. Cystoscopic view of the ostium (O) of a UD, which is often difficult to visualize endoscopically. L, lumen of the urethra.

surgical planning; however, the failure to locate an ostium on cystourethroscopy should not influence the decision to proceed with further investigations or surgical repair.

Urodynamics. For patients with UD and urinary incontinence or significant voiding dysfunction, a urodynamic study may be helpful in accurately characterizing these symptoms (Bhatia et al, 1981; Reid et al, 1986; Summitt and Stovall, 1992). Urodynamics may document the presence or absence of stress urinary incontinence (SUI) prior to repair. Approximately one third of women will present with symptoms of urinary incontinence and approximately 50% of women with UD will demonstrate SUI on urodynamic evaluation (Bass and Leach, 1991; Ganabathi et al, 1994). A video-urodynamic study is optimal as it combines both a VCUG and a urodynamic study, thus consolidating the diagnostic evaluation and decreasing the number of required urethral catheterizations during the patient’s clinical workup. For patients undergoing surgery for UD who have coexistent symptomatic SUI demonstrated on physical examination or urodynamically demonstrable SUI, or in those found to have an open bladder neck on preoperative evaluation, a concomitant anti-incontinence surgery can be offered. Multiple authors have described successful repair of UD and stress incontinence in the same operative setting (Bass and Leach, 1991; Swierzewski and McGuire, 1993; Ganabathi et al, 1994; Faerber, 1998). Synthetic materials (e.g., mid-urethral polypropylene mesh) should not be used in an anti-incontinence procedure synchronously with UD surgery because of the potentially increased risk of urethral erosion and infection (Dmochowski et al, 2010). Whether such material can be safely used months or years following successful UD surgery in patients with de novo or persistent SUI is unknown. Alternatively, a small number of patients may have evidence of bladder outlet obstruction on urodynamic evaluation because of the obstructive or mass effects of the UD on the urethra. It should be noted that SUI may coexist with obstruction (Bradley and Rovner, 2004) but, nevertheless, both conditions can be treated successfully with a carefully planned and executed operation. For patients with mild nonbothersome SUI, it is reasonable to perform urethral diverticulectomy and then re-evaluate for the development of postoperative SUI.

Urethral pressure profilometry has also been used by some authors to assess and/or diagnose patients with UD, noting a biphasic pattern or pressure drop at the level of the lesion during

Figure 90-20. Schematic diagram of a double-balloon catheter. The curved white arrow represents flow of the contrast as it enters the urethral lumen. UD, urethral diverticulum.

the study (Bhatia et al, 1981; Wagner et al, 1986; Summitt and Stovall, 1992).

Imaging

High-quality preoperative imaging is important in the diagnosis and therapy of female UD. Aside from its utility as a diagnostic entity, radiologic imaging should also provide an accurate reflection of the relevant anatomy of the UD, including its relationship to the proximal urethra and bladder neck.

Diagnostic Contrast Radiography. A number of imaging techniques have been applied to the study of female UD, and no single study can be considered the gold standard or optimal imaging study for the evaluation of UD. Each technique has relative advantages and disadvantages, and the ultimate choice of diagnostic study in many centers often depends on several factors, including local availability, cost, and the experience and expertise of the radiologist. Currently available techniques for the evaluation of UD include double-balloon PPU, VCUG, intravenous urography, ultrasonography, and MRI with or without an endoluminal coil.

Historically, double-balloon PPU had been considered to be the optimal study for the diagnosis and assessment of female UD (Davis and Cian, 1956; Davis and TeLinde, 1958; Greenberg et al, 1981; Ganabathi et al, 1994). In this technique, a highly specialized catheter (Trattner catheter) with two balloons separated by several centimeters is inserted into the female urethra (Fig. 90-20). This catheter contains a channel that exits through a side hole between the two balloons. One balloon is positioned adjacent to the external urethral meatus, and the other balloon is situated at the bladder neck. Both balloons are inflated, creating a seal about the urethral lumen. Contrast is then infused through the channel under slight pressure, distending the urethral lumen between the two balloons and forcing contrast into the UD, thereby opacifying the cavity. This highly specialized study provides outstanding images of the urethra and UD and importantly, unlike VCUG, is not dependent on the patient successfully voiding during the study. However, PPU is not widely performed clinically and the specialized Trattner catheter is only variably available.

As an alternative to PPU, VCUG may provide excellent imaging of UD (Fig. 90-21). It is widely available and is a familiar diagnostic technique to most radiologists. Sensitivity for UD with this technique varies from 44% to 95% (Ganabathi et al, 1994; Jacoby and Rowbotham, 1999). Patients often will have difficulty in initiating micturition in the radiology suite because of the pain associated with urethral catheterization, psychogenic inhibition attributable to voiding in the presence of others, or other factors. In the absence of voiding, the UD will often not be seen. Therefore a VCUG that does not demonstrate a UD but did not contain voiding images or postvoid images is nondiagnostic. If the patient is unable to

Figure 90-21. Voiding image from a voiding cystourethrogram demonstrating a urethral diverticulum (UD).

void under fluoroscopy during the VCUG, an attempt should be made to void in the privacy of an adjacent bathroom. If voiding in private was successful, a postvoid film taken under these circumstances will likely show a collection of contrast inferior to the bladder demonstrating the UD. Unfortunately, an inability to generate an adequate flow rate during the VCUG will result in suboptimal filling of the UD and an underestimation of its size and complexity (Fig. 90-22). Three-dimensional CT VCUG with reconstructions is a novel imaging technique for UD but is not yet widely available clinically (Kim et al, 2005).

Intravenous urography may be considered in patients in whom it is necessary to delineate the upper urinary tract or to evaluate for the possibility of a congenital ectopic ureteral anomaly as the cause of an anterior vaginal wall mass (Blacklock et al, 1982). The postvoid film of the urogram can be helpful for the diagnosis of UD in some patients (Stern and Patel, 1976; Goldfarb et al, 1981).

Ultrasonography. This study has been advocated for the preoperative assessment of vaginal masses and UD by multiple authors (Lee and Keller, 1977; Wexler and McGovern, 1980; Baert et al, 1992; Mårtensson and Duchek, 1994; Chancellor et al, 1995; Vargas-Serrano et al, 1997; Dmochowski, 2001; Fortunato et al, 2001; Lee et al, 2001; Gerrard et al, 2003). Abdominal, transvaginal, translabial, and transurethral techniques have been described. Transvaginal imaging often provides information regarding the size and location of UD. On ultrasonographic imaging, the UD appears as an anechoic or hypoechoic area with enhanced through-transmission. Ultrasonography is relatively noninvasive and does not expose the patient to radiation. Another significant advantage of ultrasonography is that successful imaging of UD does not require voiding. However, ultrasonography may not produce detailed high-resolution images that demonstrate precise surgical anatomy.

Magnetic Resonance Imaging. As an alternative to the radiologic investigations noted previously, MRI permits relatively noninvasive, high-resolution, multiplanar imaging of UD. UD appear as areas of decreased signal intensity on T1 images compared with the surrounding soft tissues, and have high signal intensity on T2 images. A distinct advantage of MRI compared with VCUG is that successful imaging of UD is wholly independent of voiding and that it is free from ionizing radiation. Surface coil (Hricak et al, 1991; Kim et al, 1993) (Fig. 90-23) and endoluminal (Siegelman et al, 1997; Wang and Wang, 2000; Blander et al, 2001; Lorenzo et al, 2003) techniques have been described. Endoluminal magnetic resonance imaging (eMRI) places the magnetic coil into a body

Figure 90-22. Voiding cystourethrogram (VCUG) and magnetic resonance image (MRI) from a patient with a large circumferential urethral diverticulum (UD). A, The voiding image from the VCUG shows poor opacification of the proximal urethra with suboptimal distention of the UD as a result of a poor voiding effort. B to D, The endoluminal MRI demonstrates the full extent and complexity of the lesion on the T2 axial (B), midline sagittal (C), and parasagittal (D) images.

cavity adjacent to the area of interest. This location produces an improved signal-to-noise ratio and high-resolution imaging of these areas (Siegelman et al, 1997; Blander et al, 2001) with excellent sensitivity and specificity for the diagnosis of UD (Dwarkasing et al, 2011). For the evaluation of UD, the eMRI coil is placed intravaginally or intrarectally. Both surface coil MRI and eMRI appear to be superior to VCUG and/or PPU in the evaluation of UD (Kim et al, 1993; Neitlich et al, 1998; Blander et al, 2001), but the technology is expensive and not widely available. Notably, there are several lesions, including periurethral bulking agents, that can be misdiagnosed as UD on MRI, and this imaging technique may be inadequate in the diagnosis of malignancy within UD, a rare but important finding (Chung et al, 2010).

Contraindications to MRI for UD are few; these include metallic foreign body fragments, claustrophobia, and an inability to tolerate the endoluminal probe.

Differential Diagnosis: Periurethral Masses Other Than Urethral Diverticula

Periurethral masses other than UD comprise a wide spectrum of conditions that must be differentiated from each other and UD. It may often be possible to make a definitive diagnosis based on history and physical examination alone; in other cases, judicious use of radiographic and cystoscopic studies will be necessary to exclude UD.

Vaginal Leiomyoma. Vaginal leiomyomata are benign mesenchymal tumors of the vaginal wall that arise from smooth muscle elements. They commonly present as a smooth, firm, round mass on the anterior vaginal wall (Fig. 90-24). Vaginal leiomyoma is an uncommon lesion, with approximately 300 cases reported in the literature (Young et al, 1991). In a recent series of 79 patients with periurethral masses, 4 (5%) were found to have vaginal leiomyoma

Figure 90-23. Surface coil T2 magnetic resonance image demonstrating a urethral diverticulum (arrows) in the sagittal (A) and axial (B) planes.

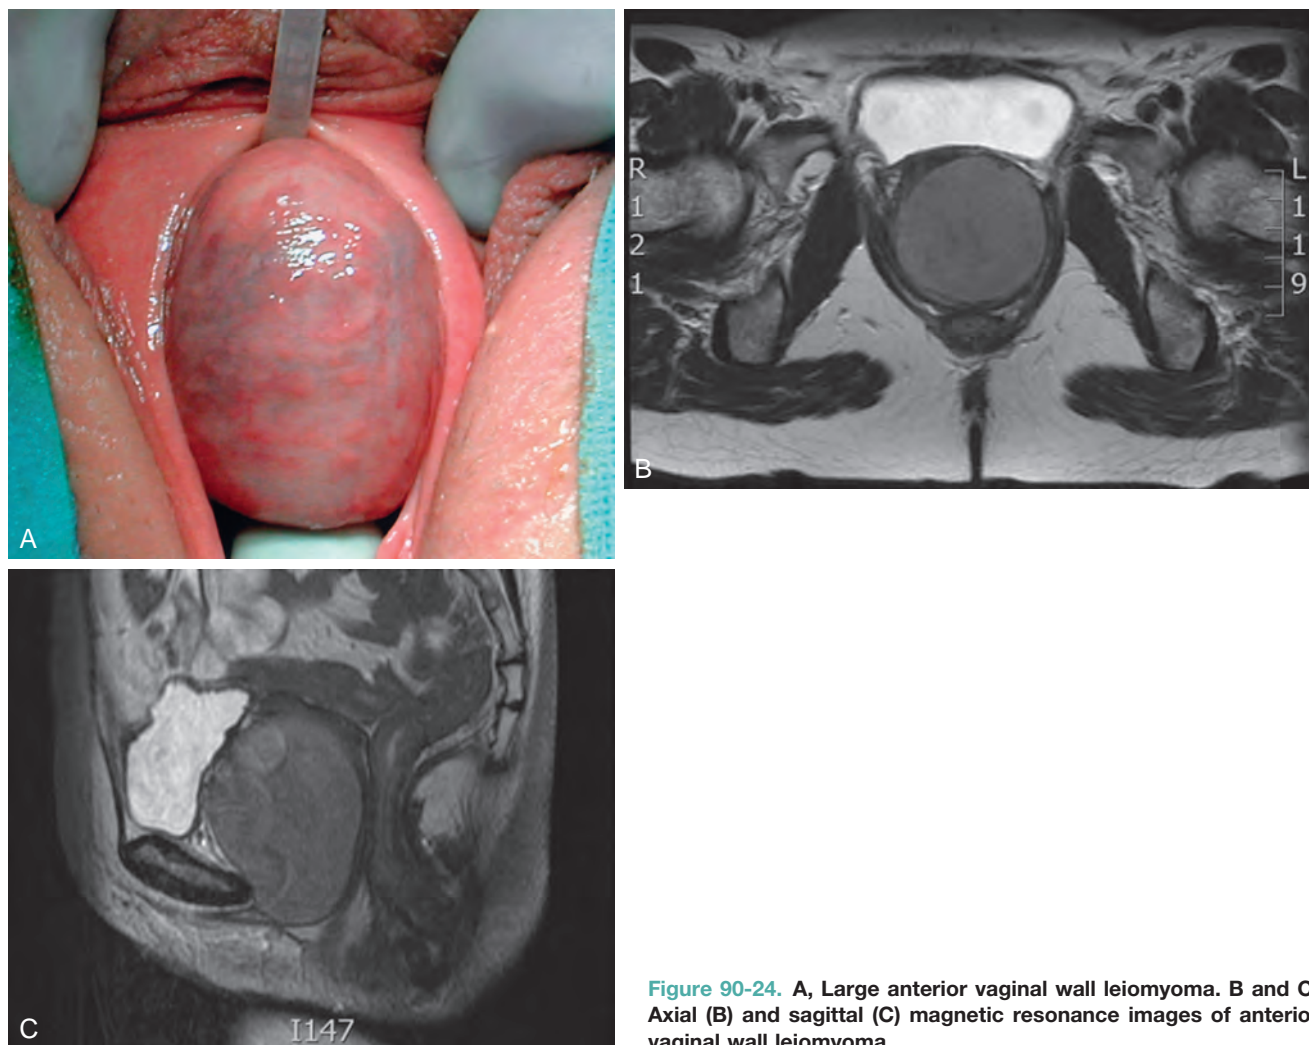

Figure 90-24. A, Large anterior vaginal wall leiomyoma. B and C, Axial (B) and sagittal (C) magnetic resonance images of anterior vaginal wall leiomyoma.

Figure 90-25. Skene gland cyst in a 19-year-old female. Note the large periurethral mass with displacement of the urethral meatus.

Figure 90-26. Upper pole ectopic ureter in a 39-year-old female being evaluated for lifelong urinary incontinence and recurrent pyelonephritis. A tubelike structure (arrow) representing the turgid, debris-filled ectopic ureter is seen on the anterior vaginal wall.

(Blaivas et al, 2004). These masses were all apparent on physical examination as freely mobile, firm, nontender masses on the anterior vaginal wall. They may be misdiagnosed as UD (Shirvani and Winters, 2000). Symptoms, if they exist, are usually related to the size of the lesion and include a mass effect, obstruction, pain, and dyspareunia. They commonly present in the fourth to fifth decade. Similar to uterine leiomyoma, these lesions are usually estrogen dependent and have been demonstrated to regress during menopause (Liu, 1988). Excision or enucleation (Young et al, 1991) through a vaginal approach is often curative and is recommended to confirm the diagnosis, to exclude malignant histology, and also to alleviate symptoms.

Skene Gland Abnormalities. Skene gland cysts and abscesses are similar lesions that are differentiated based on clinical findings (Fig. 90-25). Both lesions generally present as small, cystic masses just lateral or inferolateral to the urethral meatus. They may be lined with transitional or stratified squamous epithelium. Abscesses may be extremely tender and inflamed, and, in some cases, purulent fluid can be expressed from the ductular orifice. **Classically, in contrast to UD, these lesions do not communicate with the urethral lumen.** Skene gland cysts are not uncommonly noted in neonatal girls and young to middle-age female patients (Lee and Kim, 1992). Symptoms may include dysuria, dyspareunia, obstruction, and pain. **Differentiation from UD can often be made on physical examination, because these lesions are located relatively distally on the urethra, often distorting the urethral meatus, as compared with UD, which most commonly occur over the mid- and proximal urethra.** Various treatments for Skene gland abnormalities have been described, including aspiration, marsupialization, incision and drainage, and simple excision. Surgical excision is curative.

Adenocarcinoma arising in Skene glands has been reported. Because of homology with the prostate, these patients may demonstrate elevated prostate-specific antigen levels that normalize with treatment (Dodson et al, 1994).

Gartner Duct Abnormalities. Gartner duct cysts represent mesonephric remnants and are found on the anterolateral vaginal wall from the cervix to the introitus. Because these are mesonephric remnants, they may drain ectopic ureters from poorly functioning or nonfunctioning upper pole moieties in duplicated systems (Fig. 90-26). They have also been reported with single-system ectopia, although this is much less common in females (Gadbois

and Duckett, 1974; Currarino, 1982). It is not clear what proportion of patients with Gartner duct cysts will have ipsilateral renal abnormalities, but upper tract evaluation is recommended. In contrast, approximately 6% of subjects with unilateral renal agenesis will have a Gartner duct cyst (Eilber and Raz, 2003). Up to 50% of patients with Gartner duct cysts and renal dysplasia may also have ipsilateral müllerian duct obstruction (Sheih et al, 1998).

Treatment depends on symptoms and association with ectopic ureters. If the lesions are asymptomatic and are associated with a nonfunctioning renal moiety, they can be observed. Aspiration followed by sclerotherapy has been successful (Abd-Rabbo and Atta, 1991). Simple excision or marsupialization has also been recommended for symptomatic lesions. If the cyst is associated with a functioning renal moiety, treatment must be individualized.

Vaginal Wall Cysts. Vaginal wall cysts usually present as small asymptomatic masses on the anterior vaginal wall (Deppisch, 1975) but may enlarge to cause lower urinary tract symptoms or dyspareunia (Fig. 90-27). They may arise from multiple cell types: mesonephric (Gartner duct cysts), paramesonephric (müllerian), endometriotic, urothelial, or epidermoid (inclusion cyst). A specific diagnosis cannot be reliably made until the specimen is removed and examined by a pathologist. The histologic subtype is usually of little consequence, although epidermoid cysts are usually associated with previous trauma or vaginal surgery. Pradhan and Tobon (1986) described the pathologic characteristics of 43 vaginal cysts removed over a 10-year period from 41 women. The derivation of the cyst was müllerian in 44%, epidermoid in 23%, and mesonephric in 11%. The remainder were a Bartholin gland type, endometriotic, and indeterminate. As with other periurethral masses, they must be differentiated from UD. Treatment is usually by simple excision in symptomatic patients.

Urethral Mucosal Prolapse. Urethral prolapse presents as a circumferential herniation or eversion of the urethral mucosa at the urethral meatus. The prolapsed mucosa commonly appears as a beefy red doughnut-shaped lesion that completely surrounds the urethral meatus. It may be asymptomatic or present with bleeding, spotting, pain, or urinary symptoms. It is commonly noted in two separate populations: postmenopausal women and prepubertal

Figure 90-27. Anterior vaginal wall cyst prior to planned excision. This mass was misdiagnosed as a cystocele and followed for many years in this patient with considerable lower urinary tract symptoms. A midline incision has been marked out prior to operative repair.

girls. Although thought to be more common in young African-American girls, more recent series do not confirm this predilection (Fernandes et al, 1993; Rudin et al, 1997). In children, it is often causally related to Valsalva voiding or constipation. Eversion of the mucosa may then occur as a result of a pathologically loose attachment between smooth muscle layers of the urethra (Lowe et al, 1986). Etiology is much less clear for postmenopausal women, although it has been epidemiologically linked to estrogen deficiency. Treatment may be medical or surgical. Medical treatment involves topical creams (estrogen, anti-inflammatory) and/or sitz baths. Various surgical techniques have been described, including cauterization, ligation around a Foley catheter, and complete circumferential excision. Circumferential excision with suture reapproximation of the remaining urethral mucosa to the vaginal wall can be performed with few complications. Rudin and colleagues (1997) reported outcomes in 58 girls with urethral prolapse. Medical treatment was initially successful in 20 patients among whom there were 5 recurrences. The remaining 38 patients failed initial conservative management and underwent surgical excision with 4 complications, including urethral stenosis in 2 patients. Jerkins and colleagues (1984) found superior results in surgically treated patients when compared with medical management or catheter ligation.

Urethral Caruncle. Urethral caruncle is an inflammatory lesion of the distal urethra that is most commonly diagnosed in postmenopausal women. It usually appears as a reddish exophytic mass at the urethral meatus, which is covered with mucosa. These lesions are often symptomatic and noted incidentally on gynecologic examination. When irritated, they may cause underwear spotting or become painful. Less commonly they may cause voiding symptoms. Rarely, these lesions may thrombose, resulting in a discolored periurethral mass (Fig. 90-28). Etiologically, they are related to mucosal prolapse. Chronic irritation contributes to hemorrhage, necrosis, and inflammatory growth of the tissue that corresponds to the histology of excised lesions. If the lesion is atypical in appearance or behavior, excision may be warranted to exclude other entities. Intestinal metaplasia, tuberculosis, melanoma, and lymphoma have all been reported to either coexist with or mimic urethral

Figure 90-28. Thrombosed urethral caruncle in a postmenopausal female. The Foley catheter is seen in the urethra. Simple excision was curative.

caruncles (Willett and Lack, 1990; Indudhara et al, 1992; Khatib et al, 1993; Lopez et al, 1993; Atalay et al, 1998).

There is a paucity of literature regarding optimal treatment of urethral caruncle. Most authors recommend initial conservative management with topical estrogen or anti-inflammatory creams and sitz baths. Large or refractory lesions may be managed with simple excision. The tip of the lesions should be grasped and traction employed to fully expose the base of the caruncle. The lesion can then easily be excised. If a large defect remains, the mucosa may be reapproximated with absorbable suture. In most instances, the urethral mucosa will heal around a Foley catheter, which may be left in place for several days.

Periurethral Bulking Agents. The transurethral or periurethral injection of bulking agents for the treatment of stress incontinence may result in an anterior vaginal wall mass that appears cystic on imaging, consistent with a UD (Clemens and Bushman, 2001; Bridges et al, 2005; Castillo-Vico et al, 2007). A careful history will elicit this possibility. Typically, these lesions do not communicate with the urethra and are largely asymptomatic. Symptomatic lesions may be surgically excised transvaginally (Kumar et al, 2011).

Classification of Urethral Diverticula

Although not yet widely adopted, a classification system for UD has been proposed by Leach and colleagues (1993). This staging system for UD, termed the L/N/S/C3 classification system, is similar to that used for cancer staging and is based on several characteristics of UD, including location, number, size, anatomic configuration, site of communication to the urethral lumen, and continence status of the patient. This system attempts to standardize description of UD, but currently it has not been prospectively applied or validated by other authors. Another proposed classification scheme uses the location of the UD as the primary determinant of surgical approach, with distal lesions undergoing marsupialization and more proximal lesions undergoing excision and reconstruction (Ginsburg and Genadry, 1983).

Finally, a classification system proposed by Leng and McGuire (1998) divides UD into two categories based on the presence or absence of a preserved periurethral fascial layer. In some patients with UD who have undergone prior vaginal or urethral surgery, the periurethral fascial layer may be deficient, resulting in a pseudodiverticulum. These authors suggest that the recognition of this anatomic configuration has important implications for surgical

reconstruction. These patients may require additional reconstruction or interposition of a tissue flap or graft for reconstruction.

KEY POINTS: FEMALE URETHRAL DIVERTICULA—DIAGNOSIS

- Female UD are often diagnosed in the evaluation of nonspecific lower urinary tract symptoms, including dysuria, pelvic pain, vaginal mass, dyspareunia, and recurrent UTIs.
- Multiple imaging modalities may be used in the diagnosis and evaluation of female UD, including PPU, VCUG, ultrasonography, and MRI; each of these techniques has inherent advantages and disadvantages.
- The differential diagnosis of periurethral vaginal masses is extensive. A careful history, physical examination, and appropriate diagnostic studies will usually be adequate to provide a definitive preoperative diagnosis.

Surgical Repair of Female Urethral Diverticula

Indications for Repair

Although often highly symptomatic, not all UD mandate surgical excision. Some patients may be asymptomatic at presentation, with the lesion incidentally diagnosed on imaging for another condition

or, perhaps, incidentally noted on routine physical examination. Other patients may be unwilling or medically unable to undergo surgical removal. Very little is known regarding the natural history of untreated UD. Whether these lesions will progress in size, symptomatology, or complexity with time is unknown. For these reasons, and because of the lack of symptoms in selected cases, some patients may not desire surgical therapy. However, it should be noted that there are multiple reports in the literature of carcinomas arising in UD (Marshall and Hirsch, 1977; Prudente de Toledo et al, 1978; Tesluk, 1981; Tines et al, 1982; Patanaphan et al, 1983; Gonzalez et al, 1985; Thomas and Maguire, 1991; Rajan et al, 1993; Seballos and Rich, 1995; Hickey et al, 2000), and it is possible that certain carcinomas arising in UD are asymptomatic and may not be initially or prospectively identified on radiologic imaging (Chung et al, 2010). Thus patient counseling is necessary with patients who elect primary nonoperative management. Patients electing nonoperative management can be treated with low-dose antibacterial suppressants and digital stripping of the anterior vaginal wall following micturition to prevent postvoid dribbling and reduce the risk of UTI resulting from stasis in the UD. Whether long-term surveillance is required in these patients, with periodic physical examinations, radiographic imaging, or endoscopic examination, is unknown.

Symptomatic patients, including those with dysuria, refractory bothersome postvoid dribbling, recurrent UTIs, dyspareunia, and pelvic pain, may be offered surgical excision. Those with UD and symptomatic SUI can be considered for a concomitant anti-incontinence procedure at the time of UD excision (see later discussion) (Fig. 90-29).

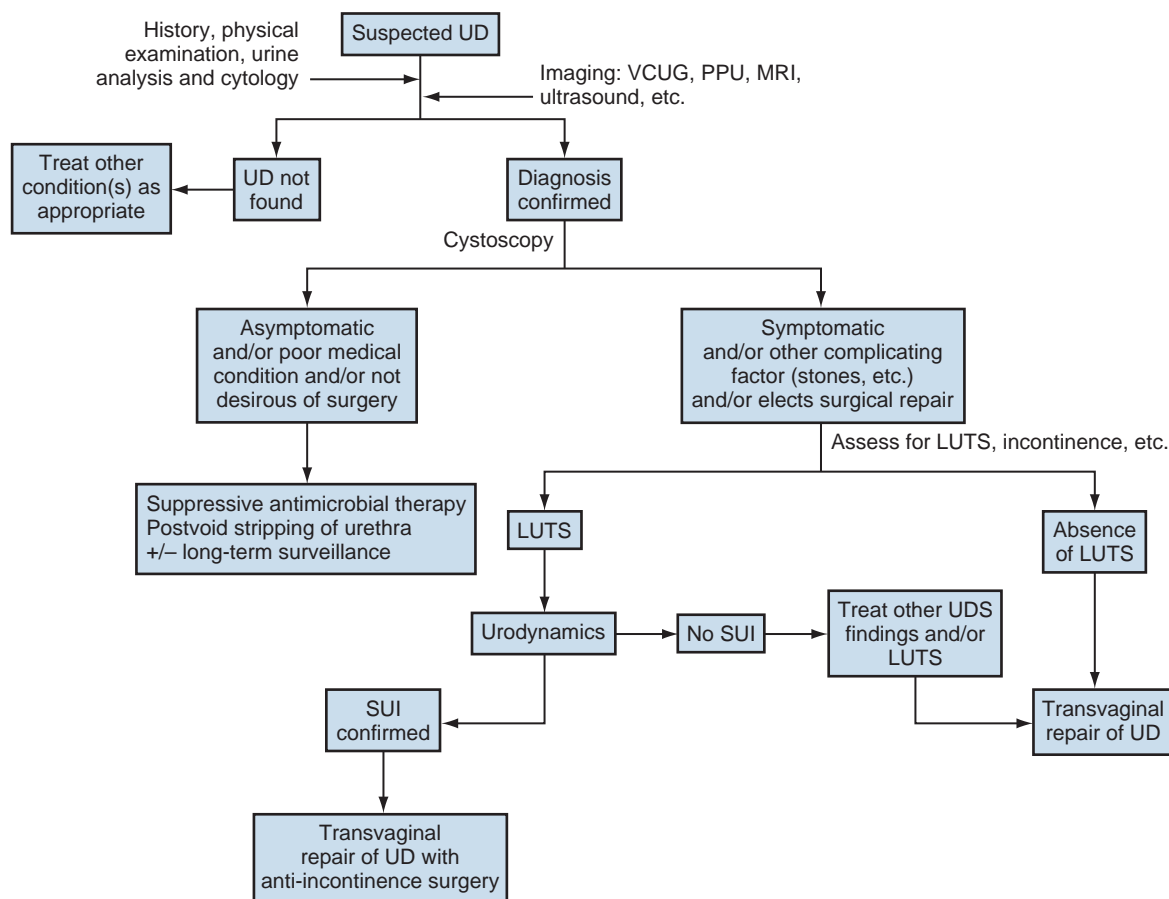

Figure 90-29. Algorithm for treatment of urethral diverticula. LUTS, lower urinary tract symptoms; MRI, magnetic resonance imaging; PPU, positive-pressure urethrography; SUI, stress urinary incontinence; UD, urethral diverticulum; UDS, urodynamics; VCUG, voiding cystourethrography.

Techniques for Repair

Alternative Techniques. A variety of surgical interventions for UD have been reported since 1805 when Hey described transvaginal incision of the UD and packing the resulting cavity with lint. Approaches have included transurethral (Davis and Robinson, 1970) and open (Spence and Duckett, 1970; Roehrborn, 1988) marsupialization, endoscopic unroofing (Lapides, 1978; Spencer and Stroom, 1987), fulguration (Saito, 2000), incision and obliteration with oxidized cellulose (Ellick, 1957) or polytetrafluoroethylene (Mizrahi and Bitterman, 1988), coagulation (Mizrahi and Bitterman, 1988), and excision with reconstruction. **Most commonly, a complete excision and reconstruction is performed as described below.** However, for distal lesions, a transvaginal marsupialization as described by Spence and Duckett may reduce operative time, blood loss, and recurrence rate (Spence and Duckett, 1969, 1970; Roehrborn, 1988). During this procedure, care must be taken to avoid aggressively extending the incision proximally, which could result in vaginal voiding or potentially damage the proximal and distal sphincteric mechanism, resulting in SUI. Another potentially significant complication with the Spence-Duckett procedure is that, in sexually active women, a pseudoseptum may be created by the marsupialization of the urethra with respect to the anterior vaginal wall, which may result in dyspareunia. Therefore this approach is probably only applicable to UD in very select cases involving the distal one third of the urethra. It is not commonly performed.

Excision and Reconstruction. Excision and reconstruction is probably the most common surgical approach to UD in the modern era. The principles of the urethral diverticulectomy operation have been well described (Box 90-2). There are only a few minor issues about which some surgeons may disagree, including the type of vaginal incision (inverted “U” vs. inverted “T”), whether it is necessary to remove the entire mucosalized portion of the lesion, and, finally, the optimal type of postoperative catheter drainage (urethra only vs. urethra and suprapubic).

Complex urethral reconstructive techniques for the repair of UD have been described. Fall (1995) described the use of a bipedicle vaginal wall flap for urethral reconstruction in patients with UD and urethrovaginal fistula. Laterally based vaginal flaps have also been used as an initial approach to UD (Woodhouse et al, 1980; Appell and Suarez, 1982). Complex anatomic configurations may exist, and many novel approaches have been described for complicated anteriorly located or circumferential lesions (Clyne and Flood, 2002; Rovner and Wein, 2003; Vakili et al, 2003).

The technique described herein is similar to that described by Leach and Raz (Leach et al, 1986), based on earlier work by Benjamin and colleagues (1974) and Busch and Carter (1973).

Preoperative Preparation. The urine should be sterile preoperatively. Surgery should not proceed in the setting of an acute UTI. Prophylactic antibiotics are often used preoperatively to ensure sterile urine at the time of surgery. Patients can also be encouraged to strip the anterior vaginal wall following voiding, thereby consistently emptying the UD and preventing urinary stasis and recurrent

UTIs. This may not be possible in those with noncommunicating UD or in those who have significant pain related to the UD. In some patients with postmenopausal atrophic vaginitis, application of topical estrogen creams for several weeks prior to surgery may be beneficial in improving the overall quality of the tissues with respect to planned operative dissection and mobilization. Preoperative parenteral antibiotics are administered especially for those with recurrent or persistent UTIs.

Urethral diverticulectomy surgery is complex and sometimes quite technically challenging. Further complicating these cases are the associated preoperative symptoms, such as pain, dyspareunia, voiding dysfunction, UTIs, and urinary incontinence. These associated symptoms are often, but not always, improved or eliminated with surgical repair despite even a technically successful surgery. Therefore the importance of appropriate preoperative patient counseling regarding surgery and postoperative expectations of cure cannot be overemphasized.

Patients with symptomatic SUI can be offered simultaneous anti-incontinence surgery. Preoperative video-urodynamics may be helpful in evaluating the anatomy of the UD, assessing the competence of the bladder neck, and confirming the diagnosis of SUI. Video-urodynamics can often accurately differentiate and characterize true SUI from postvoid dribbling, vaginal voiding, and false incontinence resulting from urine discharge from a urine-filled UD.

In patients with SUI and UD, Ganabathi and others have described satisfactory short-term results with concomitant needle bladder neck suspension in these complex patients (Lockhart et al, 1990; Ganabathi et al, 1994). More recently, pubovaginal fascial slings have been used in patients with UD and SUI with satisfactory outcomes (Swierzewski and McGuire, 1993; Faerber, 1998; Romanzi et al, 2000). As noted previously, synthetic slings should not be placed concomitantly at the time of urethral diverticulectomy (Dmochowski et al, 2010). Placement of synthetic material adjacent to a fresh suture line following diverticulectomy in the setting of potentially inflamed tissues and infected urine may increase the risk of complications, such as urethral erosion and vaginal exposure of the sling material, as well as urethrovaginal fistula formation.

Procedure. The patient is placed in the lithotomy position with all pressure points well padded. The use of padded adjustable stirrups for the lower extremities greatly enhances operative access to the female perineum. A standard vaginal antiseptic preparation is applied. A weighted vaginal speculum and Scott retractor with hooks aid in exposure. A posterolateral episiotomy may be beneficial in some patients for additional exposure, although the mid-urethral (and therefore somewhat distal in the vaginal canal) location of most UD usually precludes the need for this type of adjunctive procedure. A Foley catheter is placed per urethra. If desired, a suprapubic tube is placed at the start of the procedure, either using the Lowsley retractor or proceeding percutaneously under direct transurethral cystoscopic visual guidance. Placement of the suprapubic tube at the end of the case is not advisable because this will require traversing the fresh urethral suture line and risk disruption of the repair.

An inverted U is marked along the anterior vaginal wall with the base of the U at the level of the distal urethra and the limbs extending to the bladder neck or beyond (Fig. 90-30A). Care is taken to ensure that the limbs of the U are progressively wider proximally (toward the bladder neck) to ensure adequate vascularity at the distal lateral margins of the anterior vaginal wall flap. Compared with the inverted T incision, the inverted U incision provides excellent exposure laterally at the level of the midvagina and can be extended proximally as needed for lesions that extend beyond the bladder neck. Injectable saline can be infused along the lines of the incision to facilitate dissection. An anterior vaginal wall flap is created by careful dissection in the potential space between the vaginal wall and the periurethral fascia. The use of sufficient countertraction during this portion of the procedure is important in maintaining the proper plane of dissection. Care is taken to preserve the periurethral fascia and avoid inadvertent entry into the UD.

BOX 90-2 Principles of Transvaginal Urethral Diverticulectomy (UD)

- Mobilization of a well-vascularized anterior vaginal wall flap(s)
- Preservation of the periurethral fascia
- Identification and excision of the neck, or ostium, of the UD
- Removal of entire UD wall or sac (mucosa)
- Watertight urethral closure
- Multilayered, nonoverlapping closure with absorbable suture
- Closure of dead space
- Preservation or creation of continence

Figure 90-30. A, An inverted U incision is marked on the anterior vaginal wall. Retraction is aided by the use of Allis clamps and a ring retractor with hooks. B, After reflection of the anterior vaginal wall, a transverse incision is made in the periurethral fascia. The dotted line represents the intended incision line. C, The periurethral fascia is incised and dissected from the underlying urethral diverticulum. D, The diverticular sac is freed from the periurethral fascia. E, The urethral catheter is seen after complete excision of the diverticular sac. F, The urethra is closed with absorbable suture. G, The periurethral fascia is closed with care to obliterate any dead space. H, The anterior vaginal wall flap is advanced over the periurethral suture line and secured with running interlocking absorbable suture.

A distinct layer of periurethral fascia is usually interposed between the vaginal wall and the UD. Preservation and later reconstruction of this layer is of paramount importance to prevent recurrence, close dead space, and avoid urethrovaginal fistula formation postoperatively. Pseudodiverticula have been described wherein this layer of tissue is considerably attenuated or even absent (Leng and McGuire, 1998). In these patients, an interpositional flap or graft, such as a pubovaginal sling, may be used for reconstruction.

The periurethral fascia is incised transversely (Fig. 90-30B). Proximal and distal layers of periurethral fascia are carefully developed, avoiding entrance into the UD. The UD is then grasped and dissected back to its origin on the urethra within the leaves of the periurethral fascia (Fig. 90-30C). In many cases, it is necessary to open the UD to facilitate dissection from the surrounding tissues. The ostium or connection to the urethra is identified and the walls of the UD are completely removed. Every effort should be made to remove the entire mucosalized surface of the UD to prevent recurrence (Ganabathi et al, 1994; Fortunato et al, 2001). This may involve removing small adherent or inflamed portions of the urethral wall, especially in the area of the ostium (Fig. 90-30D). All abnormal tissue in the area of the ostium should be removed, if possible, to ensure that no mucosal elements of the UD wall remain,

which could result in postoperative urine leakage and recurrence. Elaborate methods of identifying the full extent of the UD cavity have been described, including catheterization of the UD with urinary (Moore, 1952; Kohorn and Glickman, 1992) and Fogarty (Wear, 1976) catheters, packing the UD with gauze (Hyams and Hyams, 1939), infusing and staining the UD with methylene blue (Gilbert and Rivera Cintron, 1954), and the use of silicone (Hirschhorn, 1964) or cryoprecipitate (Feldstein, 1981) to create a solid mass and ease dissection. However, these measures are mostly of historical interest only and are usually not necessary in modern UD surgery (Leach and Bavendam, 1987; Ganabathi et al, 1994).

The Foley catheter is often seen transvaginally through the operative site following complete excision of UD (Fig. 90-30E). The urethra can be reconstructed over as small as a 12-Fr Foley catheter without long-term risk of urethral stricture (Young et al, 1996) and should be closed in a watertight fashion with absorbable suture (Fig. 90-30F). The closure should be tension free. Uncommonly, a UD may extend circumferentially around the urethra and require segmental resection of the involved portion of the urethra and complex reconstruction (Tamada et al, 2000; Rovner and Wein, 2003).

The periurethral fascial flaps are reapproximated with absorbable suture in a perpendicular orientation to the urethral closure

TABLE 90-2 Complications of Transvaginal Urethral Diverticulectomy

COMPLICATION	% RANGE OF REPORTED INCIDENCE
Urinary incontinence	1.7%-16.1%
Urethrovaginal fistula	0.9%-8.3%
Urethral stricture	0%-5.2%
Recurrent urethral diverticula	10%-20%
Recurrent urinary tract infection	0%-31.3%
Other:	
Hypospadias/distal urethral necrosis	Not available
Bladder or ureteral injury	Not available
Vaginal scarring or narrowing: dyspareunia, etc.	Not available

Modified from Dmochowski R. Surgery for vesicovaginal fistula, urethrovaginal fistula, and urethral diverticulum. In: Walsh PC, Retik AB, Vaughan ED Jr, et al, editors. *Campbell's urology*. 8th ed. Philadelphia: Saunders; 2002.

line to minimize overlap and the risk of postoperative urethrovaginal fistula formation (Fig. 90-30G). Care is taken to secure the periurethral fascial flaps so that all dead space is closed.

If desired, a fibrofatty labial (Martius) flap can be harvested at this point and placed over the periurethral fascia as an additional layer of closure (Dmochowski, 2001). Indications for such a flap are not universally agreed upon. However, in those patients with poor-quality tissues, with attenuated periurethral fascia, or in whom significant inflammation is encountered intraoperatively, a well-vascularized adjuvant flap (e.g., Martius flap) may reduce the risk of wound breakdown and subsequent complications such as urethrovaginal fistula.

The anterior vaginal wall flap is then repositioned and reapproximated with absorbable suture (Fig. 90-30H). This completes a three-layer closure (four layers if a Martius flap is used). An antibiotic-impregnated vaginal pack is placed.

Postoperative Care. Antibiotics are continued for 24 hours postoperatively. The vaginal packing is removed and the patient discharged home with closed urinary drainage. Antispasmodics are used liberally to reduce bladder spasms. A pericatheter VCUG is obtained at 14 to 21 days postoperatively. If there is no extravasation, the catheters are removed. If extravasation is seen, then repeat pericatheter VCUGs are performed weekly until resolution is noted. In the vast majority of cases, extravasation will resolve in several weeks with this type of conservative management (Schwab and Rovner, 2003).

Complications. Careful adherence to the principles of transvaginal urethral diverticulectomy should minimize postoperative complications. Nevertheless, complications may arise (Table 90-2). One small series suggested that large diverticula (>4 cm) or those associated with a lateral or horseshoe configuration may be associated with a greater likelihood of postoperative complications (Porgiglia et al, 2002). Common complications include recurrent UTIs, urinary incontinence, or recurrent UD. Urethrovaginal fistula is an uncommon but distressing complication of urethral diverticulectomy and deserves special mention. A urethrovaginal fistula located beyond the sphincteric mechanism should not be associated with symptoms other than perhaps a split urinary stream and/or vaginal voiding. Therefore an asymptomatic distal urethrovaginal fistula may not require repair, although some patients may request repair. Conversely, a proximal fistula located at the bladder neck or at the mid-urethra in patients with an incompetent bladder neck will likely result in considerable symptomatic urinary leakage. These patients should undergo repair with consideration for the use of an adjuvant tissue flap, such as a Martius flap, to provide a well-

Figure 90-31. Diagrams demonstrating the importance of preserving and reconstructing the periurethral fascia. A, The periurethral fascia has been opened and the urethral diverticulum has been excised. B, The periurethral fascia has been closed.

vascularized additional tissue layer. The actual timing of the repair relative to the initial procedure is controversial. Meticulous attention to surgical technique, good hemostasis, avoidance of infection, preservation of the periurethral fascia (Fig. 90-31), a well-vascularized anterior vaginal wall flap, and a multilayered closure with nonoverlapping suture lines should minimize the potential for postoperative urethrovaginal fistula formation.

Significant postoperative de novo SUI may occur in 7% to 16% of individuals undergoing urethral diverticulectomy surgery without a concomitant anti-incontinence surgery (Han et al, 2007; Ljungqvist et al, 2007; Stav et al, 2008). However, Lee and colleagues (2008) noted some degree of de novo SUI in 49% of patients following urethral diverticulectomy, the majority of which was minor and did not require additional therapy. Only 10% of these individuals underwent a subsequent SUI operation. Risk factors for de novo SUI may include the size of the diverticulum (>30 mm) and more proximal location (Stav et al, 2008).

Persistence of Symptoms Following Urethral Diverticulectomy. Some patients will have persistence or recurrence of their preoperative symptoms postoperatively. The finding of a UD following a presumably successful urethral diverticulectomy may occur as a result of a new UD, or, alternatively, as a result of recurrence of the original lesion. Recurrence of UD may be due to incomplete removal of the UD, inadequate closure of the urethra or residual dead space, or other technical factors. The risk of long-term recurrence is approximately 10% to 20% (Lee, 1983; Han et al, 2007; Ljungqvist et al, 2007; Ingber et al, 2011). Lee (1983) noted recurrent UD in 8 of 85 patients at follow-up of 2 to 15 years from the initial UD resection, while Ljungqvist and colleagues (2007) reported recurrence in 11 of 68 patients during a 26-year follow-up. The risk of recurrence of UD following transvaginal excision may be related to the complexity of the anatomic configuration and location. Han and colleagues (2007) reported no recurrent UD in 17 patients with simple UD, but of the 10 patients with circumferential UD, recurrence was noted in 6 (60%). Notably in this series, secondary procedures were not as successful in completely removing the UD. Ockrim and colleagues (2009) similarly cured all 19 patients presenting with simple UD on the first attempt, but the 11 patients with complex anatomic configurations required a total of 17 procedures for success. Proximal location and multiple UD at presentation are also potential risk factors for recurrence (Ingber et al, 2011).

Repeat urethral diverticulectomy surgery can be challenging because of altered anatomy, scarring, and the difficulty in identifying the proper anatomic planes. Complications such as fistula and recurrence of the UD are more common in reoperative cases (Ljungqvist et al, 2007).

KEY POINTS: FEMALE URETHRAL DIVERTICULA—MANAGEMENT

- Concomitant urinary incontinence symptoms should be thoroughly investigated preoperatively, and strong consideration should be given toward surgical treatment of SUI at the time of urethral diverticulectomy.
- Transvaginal excision and urethral reconstruction is the most common approach to the treatment of UD in the female.

Artificial Urinary Sphincter Complications

Sling Complications

Long-Term Results of Artificial Urinary Sphincter and Slings

Summary

Urinary incontinence (UI), the complaint of any involuntary leakage of urine (Abrams et al, 2002), may be the result of congenital anomalies, injury, genitourinary surgery, and other conditions. The most common cause of sphincteric UI in men is radical prostatectomy, with the primary mechanism being failure to store urine secondary to inadequate resistance of the outlet sphincter. Despite improvements in surgical technique that have reduced the rate of postprostatectomy UI, the burden of disease in the United States remains high and is expected to rise because of continued large numbers of radical prostatectomy performed annually (Kowalczyk et al, 2012).

UI significantly compromises health-related quality of life in men (Coyne et al, 2003, 2012) and can be improved by surgical treatment, including transurethral bulking agents, bulbar urethral slings, and the artificial urinary sphincter (AUS). These procedures prevent involuntary urinary loss by increasing outlet resistance. Although bulking agents have been used in the past as first-line treatment for male sphincteric UI, the severity of incontinence and postsurgical scarring in the vesicourethral region after prostatectomy have made surgical correction first-line treatment for the majority of cases.

After a number of generations, several bulbar urethral slings have emerged as viable treatment options for male UI. Long-term follow-up is now available for these slings, allowing patients to make more informed decisions about treatment, particularly for mild-to-moderate incontinence. However, the AUS remains the gold standard for the treatment of UI in males because of its long-term durability and effectiveness across the spectrum of moderate and severe degrees of urinary loss.

CLASSIFICATION, PATHOPHYSIOLOGY, AND CAUSE

Urinary continence in the male depends on a compliant and contractile bladder body, functional posterior urethra including the bladder neck and prostate (internal sphincter), and an intact rhabdosphincter (external sphincter). Thus stress UI develops only in men with concomitant internal and external sphincter impairment. Internal sphincter incompetence results from pelvic surgery, bladder neck injury, specific sympathetic neuropathic dysfunction,

or embryologic disruption. Incompetence of the external sphincter occurs most frequently after radical prostatectomy, but also can result from pelvic fracture urethral injuries, traumatic and acquired myelopathy, and congenital disorders such as spinal dysraphism, sacral agenesis, and the exstrophy/epispadias complex. Table 91-1 shows conditions in which the bladder neck and rhabdosphincter may be dysfunctional or compromised. Associated bladder dysfunction including decreased compliance or detrusor overactivity (DO) may complicate or confound the diagnosis and management of male UI and requires careful evaluation (see later).

Male incontinence is rare in the general population, affecting only 5% of older men (Bortolotti et al, 2000). The incidence of UI in men parallels the rate of various surgical procedures and urologic conditions listed in Table 91-1. Incontinence after transurethral resection of the prostate (TURP) may reflect persistent bladder overactivity but rarely results from damage to the external sphincter during transurethral resection. In a large Veterans Affairs Cooperative Study (Wasson et al, 1995) the rate of de novo UI after TURP was no different from that in the watchful waiting group. The historical incidence of incontinence after radical prostatectomy varies from 2.5% to 87% (Foote et al, 1991). Progressive improvement in urinary control has been reported to occur for as long as 2 years after surgery; in one study the percentage of men who used one pad or fewer after radical prostatectomy was 71%, 87%, 92%, and 98.5% at 3, 6, 12, and 24 months, respectively (Lepor and Kaci, 2004). Nerve-sparing techniques pioneered by Walsh (Eggleston and Walsh, 1985) have been associated with a reduced incidence of postoperative UI (Wei et al, 2000a). Although the mechanism of this effect remains debated, sensory and motor pudendal innervation of the rhabdosphincter is generally preserved after radical prostatectomy; in contrast, autonomic afferent denervation and impaired membranous urethral sensitivity seems to be associated with UI after radical prostatectomy (Catarin et al, 2008). Modifications to the posterior reconstruction of the rhabdosphincter during radical prostatectomy have been proposed to accelerate return to continence, but are not associated with improved long-term continence (Rocco et al, 2012). Bladder neck stenosis is associated with a reduced continence rate after radical prostatectomy, likely as a result of secondary surgical intervention (Park et al, 2001).

TABLE 91-1 Common Causes and Mechanisms of Male Sphincteric Urinary Incontinence

CONDITION	BN/PU DYSFUNCTION	RHABDOSPHINCTER DYSFUNCTION	OVERALL RISK FOR SUI
Radical prostatectomy	Present	Significant risk	Moderate
TURP	Present	Minimal risk	Low
Pelvic fracture/urethral injury	Rare	Significant risk	Low
Myelomeningocele	At risk	At risk	Moderate
Exstrophy/epispadias	At risk	At risk	Moderate

BN/PU, bladder neck/proximal urethra; SUI, sphincteric urinary incontinence; TURP, transurethral resection of the prostate.

Contemporary series demonstrate improved continence after prostatectomy when compared to historical rates, but wide variation in reported outcomes reflect patient-specific and surgeon-specific factors as well as methodology of data collection (Flynn and Webster, 2004). Validated disease-specific questionnaires such as the UCLA Prostate Cancer Index (Litwin et al, 1998) or the Expanded Prostate Cancer Index Composite (Wei et al, 2000b) that capture symptoms of stress and urge incontinence are recommended. Rates of incontinence are higher when calculated from such self-report instruments compared to chart review or physician recorded outcomes (Carlson and Nitti, 2001; Flynn and Webster, 2004). For example, Litwin and colleagues (1995) reported that up to 40% of patients in a large cohort study complain of persistent long-term UI after radical prostatectomy. Although most patients reported mild UI, 4% complained of significant lifestyle-compromising leakage.

HISTORY AND DEVELOPMENT OF DEVICES

Devices to control UI in men have been described since antiquity (Schultheiss et al, 2000). One of the first modern prosthetic devices to treat incontinence in men was reported by Berry and associates in 1961 (Engel and Wade, 1969). This acrylic prosthesis was designed to kink and compress the bulbar urethra but poor results, pain, and fistula formation led to its abandonment (Engel and Wade, 1969). In 1970, Kaufman reported the first of several procedures to provide continence by compressing the urethra with the Kaufman I procedure. This was modified by incorporating a tetrafluoroethylene mesh tape in the Kaufman II and a silicone gel-filled hemispherical prosthesis in the Kaufman III, giving a success rate of 70%.

Slings to treat SUI in men were introduced in 1975 by Kishev, who described the placement of a pliable prosthetic “wad” under the bulbar urethra. Schaeffer and associates (1998) then described a bulbourethral sling that used bolsters suspended from the rectus fascia. Another report documented results with a composite graft of polypropylene and porcine skin collagen placed suburethrally (John, 2004). Male bulbourethral slings have continued to evolve with the development of bone screws for stable fixation of synthetic mesh to the inferior pubic ramus (InVance, American Medical Systems, Minnetonka, MN), transobturator fixation (AdVance, American Medical Systems), and a combined prepubic and transobturator sling (Virtue, Coloplast, Minneapolis, MN). The bone-anchored sling is no longer commercially available in the United States, which reduces options for complex cases involving failure of transobturator sling or AUS.

In 1976, Rosen designed the first model of an AUS, but hydraulic failure and fistula formation approached 100% and this device was abandoned (Fowler and Auld, 1985). Scott presented his initial report with the AMS 721 (American Medical Systems, Minnetonka, MN), noting a 79% success rate (Timm et al, 1976; Scott, 1978). Over the next 10 years, further developments in design of the AUS were made. The AMS 742 allowed automatic cuff closure after cuff decompression. The AMS 791 and 792 used a silicone rubber cuff and a deactivation button (Scott, 1989). The AMS 800 included the

Figure 91-1. AMS 800 (American Medical Systems, Inc.) narrow-backed artificial urinary sphincter (A); close-up view of a 3.5-cm cuff (B). Note the subtle folds of the three-cushion design unique to the 3.5-cm cuff.

deactivation button within the control pump; and in 1987, the narrow-backed cuff was introduced (Fig. 91-1A), which, by improving pressure transmission from the cuff pressure to the underlying tissue, has greatly decreased the incidence of urethral erosion and tissue atrophy (Light and Reynolds, 1992). The most recent AUS modification is the addition of the 3.5-cm cuff to the size options for the device. This has allowed placement in cases with atrophy of the urethra and revision cases necessitating placement of the cuff distally, where the urethra is naturally much smaller in diameter. The 3.5-cm cuff has very specific design characteristics (see Fig. 91-1B) that were needed to achieve a concentric compression of the urethra in this small diameter (see later). Other strategies developed to address bulbar atrophy include fascial wrapping and transcorpo-real cuff placement.

Figure 91-2. Illustrations demonstrating proposed mechanism of three major slings. A, Bone-anchored. B, Transobturator. C, Quadratic fixation.

MECHANISMS OF DEVICE ACTION

Slings have evolved from simple obstructive foreign bodies to sophisticated devices that rely on interaction with the bony pelvis to compress or reposition the male urethra (Fig. 91-2). The mechanism of continence with the bone-anchored sling was thought to be from compression of the urethra, as demonstrated by an increase in fixed resistance of the urethra (Ullrich and Comiter, 2004). Further support for this proposed mechanism was the development of techniques to optimize tensioning of the sling, which also reduce the risk for urinary retention (Comiter, 2002).

Transobturator slings are hypothesized to enhance rhabdosphincter function without significant compression. Urodynamic studies show an increase in abdominal leak point pressure without other urodynamic evidence of obstruction (Davies et al, 2009; Soljanik et al, 2011). The mechanism of action is by repositioning and lengthening the membranous urethra. Evidence for this comes from fluoroscopic studies and magnetic resonance imaging (Firoozi and Vasavada, 2009; Soljanik et al, 2013). The latter studies demonstrate an increase in membranous urethral length and elevation of the bladder neck, posterior bladder wall, and rhabdosphincter (Soljanik et al, 2013).

The Virtue sling, now commercially available in the United States, is a four-armed mesh device (quadratic fixation) that provides a long segment of urethral compression against the urogenital diaphragm and a separate elevation component because of the prepubic and transobturator arms, respectively (Comiter et al, 2012).

The AUS (AMS 800) consists of a fluid-filled cuff placed around the bladder neck or bulbar urethra, which provides a 2-cm zone of circumferential compression. The degree of compression is determined by the compliance of the pressure-regulating balloon (PRB), with the pressure selected based on patient tissue characteristics and location of the cuff. The standard PRB for bulbar AUS—61 to 70 cm H₂O—optimally balances the need for occlusion with the risk for erosion. Lower pressures provide reduced continence rates but may be advisable if risk for erosion is considered excessive. The degree

of occlusion provided by standard 61 to 70 cm H₂O is similar in magnitude to that measured in successful male sling surgery. However, when the cuff is opened, urethral resistance drops to negligible levels, thus allowing men without significant detrusor contractility to empty via straining or Credé maneuver. Interestingly, the amount of urethral lengthening achieved with the AdVance male sling, 1.2-cm post-tensioning, is significantly less compared to the 2-cm zone of compression with AUS.

EVALUATION AND DIAGNOSIS

The initial evaluation of a man with UI requires a detailed history, physical examination, and urinalysis. Complex cases of sphincteric UI also will require cystoscopy and pressure-flow urodynamics to evaluate potential bladder neck stenosis and bladder storage function, respectively. Figure 91-3 shows the overall management algorithm.

History

The medical history should focus on the type, degree, and severity of UI; previous surgical procedures; and symptoms of neurologic disease. Specific evaluation of the failed AUS will be considered at the end of this section. Differentiation between stress and urge UI is important and can be aided by the voiding diary and pad test—simple inexpensive assessments of UI that are recommended before proceeding with invasive testing (Flynn and Webster, 2004). The 2- to 7-day voiding diary reliably assesses the number of incontinence episodes and may uncover significant urgency and urge incontinence (Groutz et al, 2000). Self-reported daily pad usage varies considerably with only moderate concordance with UI volume (Dylewski et al, 2007). Thus, the 24-hour home pad weight test, which objectively measures the magnitude of the incontinence, may be helpful in directing appropriate therapy. However, because the effectiveness of current surgical therapies has not been stratified according to severity of UI, the most important

MALE SPHINCTERIC URINARY INCONTINENCE (UI)

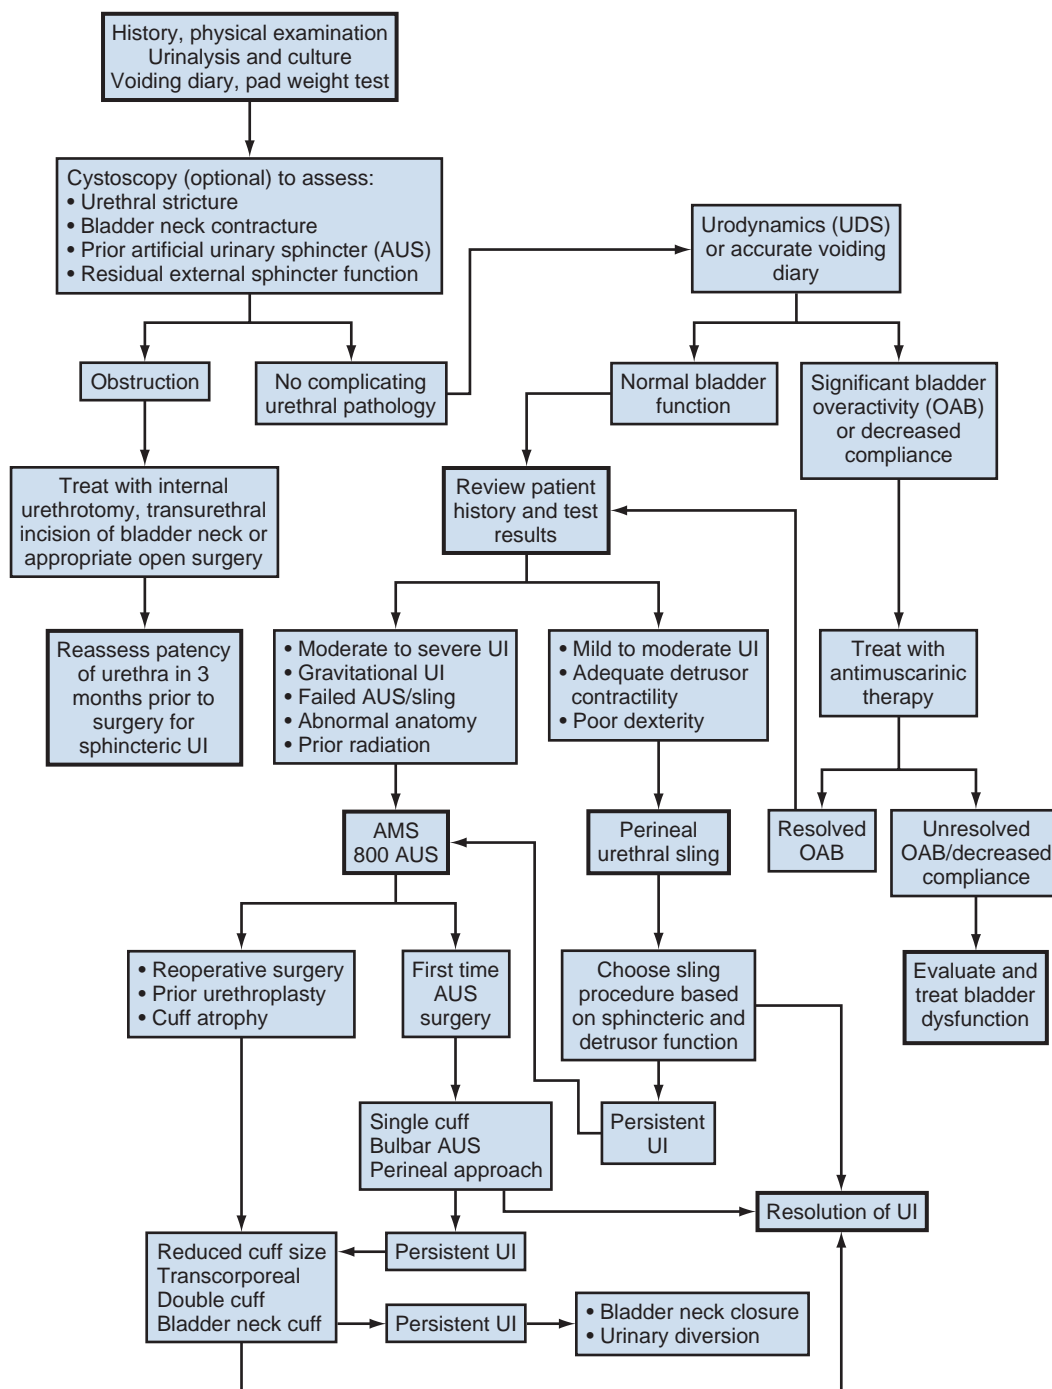

Figure 91-3. Algorithm for the evaluation and management of sphincteric urinary incontinence. OAB, overactive bladder; UI, urinary incontinence.

current use for the pad test may be as an outcome measure postoperatively. Efforts to design patient reported outcome measures that more closely correlate with pad weight and patient bother from UI will be important future directions for the field of male incontinence.

Physical Examination

A complete examination of the abdomen, back, genitalia, perineum, rectum, and neurologic system is essential to identify conditions associated with specific causes of UI. The skin should be inspected for signs of breakdown or secondary fungal or bacterial infection,

which need to be treated before surgery. Previous surgical incisions should be noted when planning AUS PRB placement. Likewise, inguinal hernias should be identified, and, if contralateral PRB placement is not possible, concomitant repair is advisable. Scrotal examination will detect pathologic processes that may influence pump placement such as hydrocele, hernias, and scrotal masses.

Laboratory

Urine analysis and culture are required before surgical correction of male UI, and all abnormalities need complete investigation.

UTI must be appropriately evaluated and eradicated. Serum creatinine and prostate-specific antigen should be obtained to assess renal function and cancer status after radical prostatectomy. Renal insufficiency requires careful evaluation before proceeding with surgical intervention.

Cystoscopy

Detection of vesicourethral anastomotic stricture, bladder neck stenosis, and bulbar urethral stricture before planned surgery may be achieved by history or uroflowmetry in most cases (Yurkanin et al, 2001). Because unrecognized urethral pathologic processes can significantly complicate all surgical approaches, endoscopic evaluation should be considered before surgical correction of UI after radical prostatectomy or TURP if there is any suspicion of bladder neck stenosis, which is rare (Wasson et al, 1995; Erickson et al, 2009; Krambeck et al, 2009). Cystoscopic evaluation of the degree of residual function of the external sphincter may help identify appropriate candidates for transobturator sling procedures (see later and Fig. 91-4). Furthermore, in patients with recurrent incontinence after AUS implantation, cystoscopy may aid in differentiating mechanical failure from other causes such as urethral atrophy. Finally, when an AUS or sling (Harris et al, 2009) has been removed because of infection or erosion, repeat evaluation of the urethra before reimplantation is recommended to identify stricture, diverticulum, and other urethral complications.

Urodynamics

Assessment of bladder capacity, compliance, and contractility is required before considering surgical correction of UI. A careful history and voiding diary may be sufficient to assess the adequacy of bladder function; noninvasive studies with uroflowmetry and postvoid residual urine volume, when normal, serve to confirm bladder capacity, completeness of bladder emptying, and the absence of bladder neck stenosis. When more comprehensive evaluation is required, however, pressure-flow urodynamics permits an accurate determination of bladder function and incontinence type and severity (Thiel et al, 2007). Intrinsic sphincteric dysfunction will be identified in almost all cases. Although 40% to 45% of men

with UI after radical prostatectomy have bladder dysfunction, it is the sole cause of incontinence in a very small percent (Leach et al, 1996; Ficazzola and Nitti, 1998). Filling cystometry can be difficult in men with severe incontinence, and occlusion of the bladder neck with a balloon catheter may be required to assess compliance and overactivity. Decreased bladder capacity was a predictor of worse outcomes from male sling surgery in one series (Warner et al, 2012). DO, although not a contraindication to surgery for UI if discovered, requires realistic counseling regarding the likelihood of successful outcome. Reduced bladder compliance presents a more serious concern, because prolonged storage at high pressures may lead to deteriorating renal function. Notably, such urodynamic findings do not reliably predict worse post-AUS continence (Trigo-Rocha et al, 2008; Lai et al, 2009). This effectiveness in spite of adverse urodynamic findings could portend silent upper tract deterioration. Conversely, detrusor hypocontractility on pressure-flow urodynamics may indicate the need for AUS if adequate detrusor function does not exist to overcome the fixed resistance of a compressive sling (Comiter, 2007).

In 2012, the American Urological Association (AUA) released guidelines on the use of urodynamics in the clinical evaluation of the patient with voiding dysfunction (Winters et al, 2012). Specific recommendations for the patient with stress incontinence include at minimum that surgeons considering invasive therapy in patients with SUI should assess the postvoid residual (PVR) urine volume. Furthermore, clinicians may perform multichannel urodynamics in patients with both symptoms and physical findings of stress incontinence who are considering invasive, potentially morbid or irreversible treatments, which include placement of the male sling or AUS.

Evaluation of Persistent Incontinence after Artificial Urinary Sphincter

The diagnostic evaluation of recurrent UI after AUS must differentiate among inadvertent deactivation, insufficient urethral compression (oversizing of cuff), mechanical failure with fluid loss, cuff erosion, bladder storage failure, urethral or bladder neck atrophy under the cuff, as well as rare causes such as a plugged delay-fill resistor or kinked tubing (Montague and Angermeier, 2001). The evaluation includes the same general approach described for de novo UI in Figure 91-3. A history of sudden loss of continence suggests deactivation or mechanical failure. Active cycling of the device excludes inadvertent deactivation. If the pump is deactivated with inadequate fluid to cycle, passive filling can be achieved by squeezing the pump on its lateral edges or by pushing on the pump with a cotton-tipped applicator opposite the deactivation button. Fluid loss from the device implies mechanical failure and leak. Plain radiography (for contrast-filled systems) or ultrasonography (for saline-filled systems) of the PRB during cycling can help differentiate fluid loss from cuff atrophy. If the PRB size changes with cycling and refills passively, mechanical failure is less likely and thus suggests cuff atrophy (Taylor and Lebowitz, 1985; Lorentzen et al, 1987). Cystoscopy, in addition to excluding erosion, can be used to visualize the cuff during cycling and give insight into the likelihood of atrophy. Urodynamics should be performed when bladder storage failure is suspected.

Figure 91-4. Appearance of external sphincter of a man with post-prostatectomy urinary incontinence showing incomplete circumferential coaptation. Such a patient would not be an ideal candidate for the transobturator sling, which relies on repositioning of a functional external sphincter unit.

KEY POINTS: INITIAL EVALUATION

- A careful history and voiding diary characterize the type and severity of UI in most men.
- Urinalysis (and culture if indicated) is required before surgical treatment.
- Suspected outlet obstruction, significant bladder overactivity, or impaired bladder contractility should prompt cystoscopy and/or urodynamic studies.

INDICATIONS FOR SURGERY

Surgical correction of UI is indicated in male patients with irreversible sphincter incompetence and bothersome involuntary leakage of urine. Although all men should complete a course of pelvic floor exercise, evidence to support the value of extensive or one-to-one pelvic floor muscle training after radical prostatectomy or TURP is lacking (Campbell et al, 2012). Because progressive improvement in continence occurs after radical prostatectomy, some authors recommend a 1-year observation period (Peyromaure et al, 2002; Flynn and Webster, 2004). However, it is unnecessary to delay intervention for patients with severe or gravitational UI who show no improvement beyond 6 months, particularly if cystoscopy shows a significant external sphincter defect. Because of limited efficacy, submucosal bulking agents are not part of the treatment algorithm for UI after radical prostatectomy (Kuznetsov et al, 2000; Montague and Angermeier, 2000; Abrams et al, 2009; Herschorn et al, 2010). Thus, the AUS and slings should be considered as first-line surgical therapy for sphincteric incontinence in most men, although a trial of a bulking agent may be appropriate in cases of neurogenic male stress UI.

Once the diagnostic evaluation has been completed (see Fig. 91-3), the best option for a given patient can be selected. Factors to consider include the severity of UI and associated bother; patient characteristics, including body mass index, prior surgical procedures, adjuvant radiation therapy, bladder function, and cystoscopic findings; manual dexterity and cognitive function; efficacy of the various implants; long-term risk for complications and reoperation; and patient preference. Absolute contraindications to surgical correction of male UI are few and include bladder disorders that jeopardize renal function, such as diminished vesical compliance and vesicoureteral reflux at low intravesical pressure. Inadequate tissue integrity at the bladder neck or urethra to accommodate a sling or AUS may require bladder neck closure or urinary diversion. Additionally, urinary tract abnormalities that require future transurethral management, such as bladder cancer or refractory vesicourethral anastomotic strictures, should be considered relative contraindications to surgery. In such cases, an AUS or sling procedure could impair transurethral access and repeated instrumentation may put the devices at risk for infection or erosion. Although metastatic prostate cancer is not a contraindication to surgical correction of UI, improvements in quality of life must be balanced against performance status and life expectancy.

The AUS remains the established device for treatment of moderate-to-severe UI, supported by numerous publications documenting its benefits. Advantages include reproducible and reliable outcomes, ability of patients to empty the bladder without detrusor contraction, and proved efficacy after pelvic irradiation. A national study using validated questions from the UCLA Prostate Cancer Index provides useful data on AUS results (Dalkin et al, 2003). After AUS, few men have severe degrees of incontinence (9%) but many continue to use pads and report a moderately high urinary bother. There is accumulating data that men who are completely dry after radical prostatectomy have significantly better health-related quality of life compared to those who wear one pad daily (Cooperberg et al, 2003). Whether this is also the case after AUS remains unknown. Long-term durability of the AUS is well established, although a revision rate of 16% and 28% at 2 and 5 years, respectively, highlights the limitations of the devices (Dalkin et al, 2003) and is consistent within a large single-institution series in which 72% had the original sphincter in place and functioning at a mean follow-up of 69 months (Elliott and Barrett, 1998).

Perineal slings have emerged as an alternative to AUS for mild-to-moderate male stress UI. A transobturator sling introduced by AMS (AdVance) has been shown to be effective in short-term to intermediate-term follow-up of well-characterized case series (two). In these selected populations, approximately 75% of patients are cured or significantly improved, with results persisting at 12 to 36 months. Thus, male sling procedures represent a significant addi-

tion to the surgical armamentarium for UI by providing an alternative to AUS for mild-to-moderate UI.

Slings can be seen as alternatives for those who refuse AUS from fear of infection, erosion, or mechanical failure, as well as those with limited physical or cognitive capacity. Comiter (2007) notes that the techniques differ in their indications, relative success rates, and complication rates for patients with varying degrees of incontinence. The trade-off between risk and efficacy must be considered, with most authors recommending AUS for more severe UI. For mild UI, bulbar sling procedures become viable alternatives, whereas AUS may represent therapeutic overkill. Thus, the bone-anchored and transobturator slings primarily should be used in cases with mild-to-moderate incontinence, which can be defined as a 24-hour pad weight of less than 150 g for mild UI (Flynn and Webster, 2004) and less than 400 g for moderate UI (Fischer et al, 2007; Collado Serra et al, 2013). A sling procedure should not be offered to those with prior radiation therapy or urethral erosion as the degree of urine loss that exists in this group usually exceeds the limits of the procedure (Schaeffer et al, 1998; Dikranian et al, 2004; Castle et al, 2005; Giberti et al, 2009; Torrey et al, 2013).

When deciding between the two devices (AUS vs. the male sling), men will follow surgeon recommendations. However, when given the choice, men will most often choose the sling, to avoid the perceived risks for mechanical malfunction, revision surgeries, and device-associated problems (Kumar et al, 2009). This tendency may lead to a higher rate of failure with slings. In light of these choices made by patients and clinicians, a subset of patients will require reoperation after placement of a transobturator male sling because of inadequate treatment of incontinence.

KEY POINTS: IMPLANT SELECTION

- Surgical intervention is indicated for stress UI resulting from intrinsic sphincteric dysfunction that fails to improve with conservative management.
- Implant selection depends on the severity of UI, prior surgical procedures, bladder function, cystoscopic findings, manual dexterity and cognitive function, long-term risk for complications and reoperation, and patient preference.
- Slings should not be used in cases of radiation and severe gravitational UI.
- AUS should not be used in cases of poor manual dexterity, cognitive disability, poor urethral tissue integrity, or severely reduced bladder compliance

TECHNIQUE OF IMPLANTATION

Operative Preparation

The entire operative site is shaved and an antiseptic skin preparation is performed, including the lower abdomen, genitals, and perineum. Surgery is conducted under general or spinal anesthesia with the patient in the low lithotomy position. Intravenous antibiotics including an aminoglycoside (gentamicin or tobramycin 5 mg/kg) and a first- or second-generation cephalosporin or vancomycin are administered within 60 minutes before skin incision according to AUA Guidelines on antimicrobial prophylaxis (Wolf et al, 2008). A chlorhexidine scrub for 10 minutes followed by iodine povacrylex (0.7% available iodine) and isopropyl alcohol, 74% weight to weight (DuraPrep, PPG Industries, Pittsburgh, PA), was shown in one recent study to reduce postpreparation bacterial skin culture rates compared to povidone-iodine, although clinical implant infection rates were similar between groups (Yeung et al, 2013). The patient is then carefully draped; a urethral catheter may be placed to drain the bladder and facilitate identification and dissection of the urethra.

Artificial Urinary Sphincter

The AUS cuff is most commonly placed around the bulbar urethra via a perineal incision. The aim is to place the cuff as proximal on the bulbar urethra as possible, proximal to the fusion of the two corporeal bodies (Fig. 91-5A). This location allows safe circumferential dissection of the urethra, provides protection of the cuff from

activation while sitting, and exposes the largest diameter of corpus spongiosum for placement of the cuff. A transscrotal approach was popularized by Wilson and associates (2003) but demonstrated suboptimal results for the control of incontinence and required modification (see later).

After incision of the skin, Colles fascia, and bulbospongiosus muscle, the Buck fascia is incised as it reflects off the bulbar urethra

Figure 91-5. Perineal anatomy and bulbar urethral dissection. A, Preferred location for first-time bulbar cuff proximal to convergence of corpora cavernosa. Note box indicating ideal cuff placement. B, Exposure of the corpus spongiosum after division of the bulbospongiosus muscle. C, Dissection at interface between spongiosum and right crus of the cavernosum. D, Dissection at interface between spongiosum and left crus of the cavernosum. AUS, artificial urinary sphincter.

Figure 91-6. Appropriate appearance of cuff. **A,** Perineal placement encircling the bulbar urethra. **B,** Endoscopic appearance with cuff activated.

onto the diverging corporeal bodies (see Fig. 91-5B to D). A 2-cm-wide tunnel is created under direct vision using sharp dissection, dorsal to the Buck fascia over the roof of the urethra. A right-angle clamp is then passed through this tunnel. Blunt spreading dissection is discouraged in this area because it risks injury to the urethra, especially in reoperative cases. **The circumference of the urethra is measured around the corpus spongiosum to guide selection of cuff size, most commonly 4 or 4.5 cm.** The urethral catheter should be removed before measurement. Although some authors advocate selecting a cuff size 0.5 to 1 cm smaller than the measured circumference of the urethra to compensate for postoperative sub-cuff atrophy of the spongiosum, the best test of cuff fit is the visual and endoscopic appearance after it has been placed around the urethra (Fig. 91-6). If the cuff size is obviously incorrect, the appropriate next size should be selected. The tubing from the AUS cuff is passed through the overlying bulbospongiosus muscle into the deep perineal space beneath the Colles fascia.

The cuffs are available in various sizes starting at 3.5 cm and range up to 11 cm (3.5, 4, 4.5, 5, 5.5, 6, 6.5, 7, 7.5, 8, 9, 10, 11 cm). The larger sizes are reserved for bladder neck implantation. The 3.5-cm cuff allows the surgeon to further downsize devices to obtain better urethral coaptation in patients with significant urethral atrophy from radiation or prior AUS placement and those needing very distal placement of cuffs because of multiple revisions. Use of this new smaller size has resulted in similar outcomes with minimal additive complications such as erosions and pain (Hudak and Morey, 2011).

Pressure-Regulating Balloon

The placement of the PRB may be achieved through a scrotal, perineal, or abdominal incision, depending on prior surgical incisions, body habitus, and surgeon preference. Implanters should be familiar with each approach. For abdominal placement, a horizontal lower quadrant incision is made in the abdomen ipsilateral to pump placement. The rectus or external oblique fascia is incised, allowing the surgeon to split the underlying muscle and access the preperitoneal or intraperitoneal space. Digital dissection creates the space required for the PRB, which is small. **We place a 61- to 70-cm H₂O PRB in all bulbar AUS and reserve the 71- to 80-cm H₂O PRB for bladder neck cuff placement.** The abdominal wall fascia is closed around the tubing.

Alternatively, the PRB can be placed via the external inguinal ring, using techniques adapted from penile implant surgery. Using either a transverse scrotal or perineal incision, the external ring is identified and used to provide access to the retropubic space by penetrating through the floor of the inguinal canal with a fingertip

or instrument. No sutures are required because the transversalis fascia provides a natural barrier to PRB extrusion. Contraindications to this approach include mesh hernia repairs, radical cystectomy, and other extensive abdominal surgery. In such cases, the abdominal approach reduces the risk for bladder or intestinal injury.

The PRB is filled with 23 mL of sterile normal saline or contrast material, unless a bladder neck cuff is used, which requires additional fluid volume according to manufacturer instructions. Filling solutions include 0.9% normal saline, Cysto-Conray (Mallinckrodt Pharmaceuticals, St. Louis, MO) 60 mL of contrast diluted with 15 mL of sterile water, or Hypaque (GE Healthcare, Wauwatosa, WI) 25% 50 mL contrast diluted with 60 mL of sterile water. To provide an isotonic solution, contrast solutions always should be diluted with sterile water. Contrast media are contraindicated if the patient has an iodine or contrast allergy.

Control Pump Placement

The pump assembly is placed into the anterior scrotum from the inguinal, scrotal, or perineal incision. When the PRB has been placed abdominally, dissection proceeds inferiorly to the scrotum above the abdominal wall fascia accessing the anterior scrotum deep to the Scarpa fascia. A finger placed outside the dependent portion of the scrotum then invaginates this skin upward into the inguinal incision, allowing the fascial layers to be stripped off the dartos layer with an instrument, creating a small pocket for the pump (Fig. 91-7). The pump is then placed into that position with the tubing held loosely with a Babcock clamp. For the single-incision approaches, a small sub-dartos pouch is created directly from the scrotal or perineal incision, orienting the pump accordingly toward the foot (scrotal) or head (perineal), respectively.

Making the Connections

Connections typically are made in the abdominal incision, when used, protecting the connections from excess wear and allowing easy exploration at a later date. **The quick connectors supplied by the manufacturer provide excellent, secure, and watertight connections for newly implanted devices.** However, they cannot be used for revision surgeries because a biofilm on the tubing interferes with watertight connection. Therefore one must use hand-tie connectors in revision cases in which the entire device is not being replaced. After completing the connections, the device is cycled several times through the activation and deactivation states. We verify adequate coaptation of the urethra via urethroscopy. The closed cuff should cause slight blanching of the urethral tissue, indicating adequate urethral coaptation, filling, and connection of

Figure 91-7. Placement of the pump beneath the skin in a sub-dartos pocket.

the device (see Fig. 91-6B). Conversely, the deactivated cuff should not cause complete coaptation. If coaptation is deemed excessive in this circumstance, replacement with a larger diameter cuff should be considered.

Tandem Cuff Artificial Urinary Sphincter

Up to 11% of men may have significant incontinence after single-cuff AUS placement, despite significant improvements in AMS 800 design and implantation techniques (Montague and Angermeier, 2000). In such patients, when the cause of persistent UI is incomplete urethral occlusion, the addition of a second cuff around the bulbar urethra (Fig. 91-8A and C) can yield satisfactory continence (Brito et al, 1993; Kabalin, 1996; DiMarco and Elliott, 2003; O'Connor et al, 2003). Indiscriminate use of the tandem cuff approach as first-line surgical treatment should be tempered by higher rates of erosion associated with the distal cuff in several series (Kowalczyk et al, 1996a; Bell and Mulcahy, 2000).

Placement of the second cuff can be accomplished via the perineal incision. After circumferentially dissecting around the distal bulbar urethra, at least 1.5 to 2 cm distal to the primary cuff, a new

Figure 91-8. Diagram of the artificial urinary sphincter (AUS), including perineal (A), scrotal (B), tandem (C), and transcorporeal (D) approaches. Note the incorporation of the ventral tunica albuginea with the corpus spongiosum in the transcorporeal approach.

cuff, usually 4.0 cm, is placed. **Connection to the existing device requires division of the existing cuff tubing and use of a metal Y connector.** An additional 3 mL of fluid must be added to the system. When adding a new cuff to an existing system, the tubing must be connected with hand-ties, as described earlier. The entire device is left deactivated for 6 weeks postoperatively.

Transcorporeal Artificial Urinary Sphincter Cuff

The transcorporeal placement of the AUS provides another approach to difficult initial or revision surgery (Guralnick et al, 2002). Rather than dissecting between the corpus spongiosum and the ventral cavernosa, parallel longitudinal incisions in the tunica albuginea of the corpora cavernosa, near the interface with the corpus spongiosum, allow the plane of dissection to pass through the septum of the corpora from one side to the other. This technique leaves the ventral tunica albuginea attached to the dorsum of the spongiosum (Fig. 91-8D). The lateral edges of the tunica albuginea may need to be imbricated *behind* the cuff; preplacement of sutures to accomplish this is advisable. **Advantages of the transcorporeal approach include reduced risk for urethral injury during reoperation after prior erosion or urethra injury; better cuff fit because of the increased bulk of the urethra; and potential reduction in erosion risk** (see Fig. 91-8). The technique is particularly useful when proximal cuff atrophy occurs under a narrow (e.g., 4.0 cm) cuff. Transcorporeal placement 2 to 3 cm distally, leaving an intervening segment of normal urethra, may yield AUS continence results similar to those in Table 91-2. Webster and associates reported a cure and improvement rate of 84% without intraoperative urethral injuries or postoperative urethral erosions at a mean follow-up of 17 months (Guralnick et al, 2002). An operative video in the AUA video series details the technique. Literature on the effectiveness of this approach remains sparse (Smith et al, 2013).

Transscrotal Artificial Urinary Sphincter

Wilson and associates (2003) described a technique in which all components of the AUS are placed through a transverse scrotal incision. Originally developed for reoperative surgery because of urethral atrophy, it allowed placement of a more distal cuff in tandem or with the transcorporeal technique (see Fig. 91-8B). Although the initial report was favorable in terms of continence outcomes, several reports suggest that the transscrotal technique yields inferior continence results (Stone et al, 2003; Henry et al, 2008). One possible explanation is that it does not allow equivalent placement of the cuff around the proximal, larger diameter bulbar urethra when compared to the perineal approach. Corroborative evidence comes from data on implanted cuff size. In the Mayo Clinic experience, 267 of the 272 perineal cuffs measured 4.5 cm and the remaining cuffs were 5.0 cm (Elliott and Barrett, 1998). Conversely, in the transscrotal series 32 of the 37 cuffs measured 4.0 cm and the remaining cuffs were 4.5 cm (Wilson et al, 2003). A modified version of the transscrotal approach, using enhanced exposure (Wilson et al, 2010), has allowed the use of larger cuff sizes around

the proximal bulbar urethra and may address the concerns raised in the literature.

Bladder Neck Artificial Urinary Sphincter

Bladder neck AUS remains an optional, although more invasive, method of cuff placement in men with sphincteric UI in whom the prostate is without external surgical or traumatic disruption. Thus, for causes of myelomeningocele and other neuropathic disorders, it should be considered as an alternative to bulbar AUS (Herndon et al, 2003). Its use is contraindicated after radical prostatectomy. Advantages include lower likelihood of erosion and cuff atrophy. Placement of the cuff is more complex, requiring a lower abdominal incision, exposure of the bladder base, and circumferential dissection of the vesicoprostatic junction. Opening the endopelvic fascia helps develop the plane of dissection; a catheter placed in the urethra and another in the rectum helps in identifying these structures. If necessary, cystostomy with placement of a finger in the lumen of the bladder neck also may assist the dissection. The bladder neck in adults requires a much larger cuff implant (usually ≥ 8 cm), higher PRB pressure (usually 71 to 80 cm H₂O), and a larger fluid volume in the system. Manufacturer packaging includes details relevant to implantation. In children, cuff and PRB characteristics may need to be altered significantly (Ruiz et al, 2006).

KEY POINTS: IMPLANTATION OF ARTIFICIAL URINARY SPHINCTER

- Standard implantation of the bulbar AUS places the cuff around the corpus spongiosum proximal to the convergence of the corporeal bodies.
- PRB of 61 to 70 cm H₂O is advised for all bulbar urethral cuffs; placement may be via abdominal, scrotal, or perineal approach.
- Postoperative deactivation of the cuff for 4 to 6 weeks is essential for proper healing without erosion.
- Prolonged urinary retention requires suprapubic cystostomy drainage.
- Revision surgery for nonmechanical causes may require modified cuff placement using 3.5-cm cuff, tandem cuff, or transcorporeal placement.

Transobturator Bulbourethral Sling

Rehder and Gozzi (2007) described a male transobturator sling that provides an alternative surgical technique for suburethral placement. Its use has been primarily for UI after radical prostatectomy. **Transobturator male slings are designed to reposition and lengthen the membranous urethra.** After exposing the corpus

TABLE 91-2 Outcomes and Complication Rates of Surgical Therapy for Mild-to-Moderate Male Sphincteric Urinary Incontinence

†Defined as no pads. Not included are results from series that included higher proportion of men with history of adjuvant radiotherapy.

spongiosum in a manner identical to that in the AUS described earlier, the space between the corpus spongiosum and corpora cavernosa is developed on each side. The corpus spongiosum is dissected along its ventral surface proximally to the level of the perineal body, which is marked to facilitate later sling positioning. The corpus spongiosum is released from the bulbospongiosus muscle to allow appropriate repositioning with tensioning of the sling. Using the inferior margin of the adductor longus muscle as a landmark, a small stab wound is made approximately 1 fingerbreadth below the muscle on each side. A spinal needle locates the obturator foramen immediately lateral to the pubic ramus. Then, using an outside-inside direction, the appropriate left- or right-sided helical passing device is inserted from the thigh through the obturator foramen and out of the perineal wound medial to the ipsilateral corporeal body. This needle should be brought out as close as possible to the superior aspect of the triangle formed by the corpus spongiosum and the pubic ramus. Once this has been completed bilaterally, the polypropylene mesh is loosely positioned in the perineum, attached to the passing devices, and pulled out of the obturator foramen to the medial thigh without tension. **The mid-portion is placed on the corpus spongiosum (Fig. 91-9A), fixed to the corpus spongiosum with four to six permanent or absorbable sutures, and the arms of the sling are pulled up to tension the device. With tensioning, the perineal body and proximal bulbar urethra should move proximally and cephalad 3 to 4 cm to achieve appropriate positioning (see Fig. 91-9B). The maneuver is performed during cystoscopic visualization of the external sphinc-**

ter region to confirm the repositioning of the urethra (see Fig. 91-9C and D). Once in position, final tensioning is achieved after removing the plastic covering of the sling arms. The tail ends of the sling are tunneled by pulling the device ends into the main perineal incision without trimming excess length. The perineal incision is closed in layers including the bulbospongiosus muscle, Colles fascia, and skin. Overnight catheter drainage is usually sufficient for decompression of the bladder.

Bone Anchor Bulbourethral Sling

The bone-anchored perineal sling popularized using the AMS InVance implant is a synthetic mesh device placed outside the bulbospongiosus muscle and attached to the pubic rami. A vertical perineal incision centered over the bulbar urethra exposes the bulbospongiosus muscle and the medial aspect of each inferior pubic ramus (Fig. 91-10A). Three titanium bone screws preloaded with a pair of 1-0 polypropylene sutures are inserted in the antero-medial aspect of each descending pubic ramus using a bone drill (see Fig. 91-10B). The proximal bone screws are placed just beneath the junction of the descending ramus and pubic symphysis, and the distal screws are inserted approximately 3 cm caudally, at the level of the bulbar urethra. **Comiter and associates (1997) described retrograde leak point pressure (RLPP) to tension the device.**

A 4- by 7-cm sling composed of synthetic or organic material is secured to the bone-anchored sutures by passing the sutures through the sling with the aid of an 18-gauge needle, 0.5 cm from the right

Figure 91-9. Transobturator sling. A, Perineal appearance of sling in place on corpus spongiosum before tensioning. B, Perineal appearance of sling after tensioning. C, Endoscopic appearance before tensioning. D, Endoscopic appearance after tensioning.

Figure 91-10. Bone-anchored sling insertion. **A**, Exposure of the right crus of the corpus cavernosum with bulbospongiosus muscle retracted medially. **B**, Screw insertion into inferior pubic ramus. **C**, Placement of the right side of the synthetic mesh device. **D**, Initial tensioning with sutures on the left side of the sling.

edge, equally spaced along the width of the sling. The right-sided sutures are then tied down to the bone (see Fig. 91-10C). With the sling positioned over the bulbospongiosus muscle, the contralateral sutures are passed through the left side of the sling and secured with a single throw of the suture over a silk safety tie. RLPP is repeated, allowing sling tension to be adjusted by moving the left-sided sutures more medially (tighter) or laterally (looser) until a RLPP of 60 cm H₂O is achieved (see Fig. 91-10D). The wound is irrigated and closed in two layers. The catheter is removed in the recovery room or the following morning for a trial of voiding.

Determining the appropriate tension of the sling is the most critical portion of the operation. Although the original choice of 60 cm H₂O was based on the pressure range of the AUS PRB, subsequent studies have demonstrated that patients who achieve an RLPP of 60 cm have better outcomes than those who demonstrate a lower compression pressure (Ullrich and Comiter, 2004). Alternative methods of sling tensioning have been described, such as an intraoperative cough test to determine sling tensioning (Madjar et al, 2001; Rajpurkar et al, 2005). When used as a salvage procedure after failed prior AUS or other sling, or in cases in which more severe incontinence is treated by inducing urinary retention, the sling is tightened as much as possible without regard to RLPP.

Other Devices

A sling with emerging clinical data, Virtue has two lateral strips for transobturator urethral elevation in addition to two prepubic arms designed to provide concomitant compression (see Fig. 91-2). This quadratic fixation has yielded acceptable early results (Comiter, 2007). The device has been approved by the U.S. Food and Drug Administration (FDA) and is marketed by Coloplast (Comiter et al, 2012). Its role in the treatment armamentarium has not been clearly defined, but because of its compressive mechanism the device potentially can be used for more severe cases of UI in a wider spectrum of causes in addition to radical prostatectomy.

The Prostate Adjustable Continence Therapy device (ProACT; Uromedica, Plymouth, MN) consists of two balloons, placed on both sides of the bladder neck to increase outlet resistance. Percutaneous adjustment of the pressure applied to the bladder neck is performed through titanium ports within the scrotum. Hübner and Schlarp showed significantly improved continence as they used this device over time, which stimulated the use of the ProACT device in centers in Europe (Hübner and Schlarp 2005; Trigo-Rocha et al, 2006). A trial in the United States has been registered with the FDA, but its recruitment status is unknown (ClinicalTrials.gov, accessed 13.11.26).

KEY POINTS: SLING INDICATIONS AND MECHANISMS

- Male bulbar urethral slings are indicated in men with mild-to-moderate sphincteric UI, intact bladder contractility, and well-vascularized urethral anatomy.
- Transobturator slings reposition and elongate the membranous urethra and depend on the intact external sphincter.
- Bone-anchored slings provide a compressive mechanism of continence and require specific protocols for tensioning.
- Quadratic fixation provides an alternative to the two-arm devices, with limited data on efficacy and durability.

ARTIFICIAL URINARY SPHINCTER COMPLICATIONS**Urinary Retention**

Urinary retention after AUS is rare, but is more frequent with transcorporeal and 3.5-cm cuffs compared to larger cuffs (Smith et al, 2013); in the immediate postoperative period it should be managed by transurethral bladder drainage with a small (10 or 12 Fr) catheter for 24 to 48 hours. Cuff deactivation must be confirmed before catheterization. If the patient fails a voiding trial at 48 hours, suprapubic cystostomy drainage is recommended to reduce the risk for urethral erosion. Ultrasound or fluoroscopic guidance is recommended to prevent puncture or potential contamination of the PRB. Retention persisting beyond several weeks implies undersizing of the cuff; in such cases, reoperation and cuff replacement may be required. Correlation with preoperative urodynamic findings is advised in such cases. Late-onset urinary retention mandates endoscopic and urodynamic evaluation to rule out proximal urethral obstruction, erosion, or detrusor failure.

Artificial Urinary Sphincter Infection

Infection remains a serious and devastating complication of any implant surgery. The rate of infection with initial AUS surgery is 1% to 3% (Gundian et al, 1989; Marks and Light, 1989; Litwiller et al, 1996; Montague and Angermeier, 2000) but may be as high as 10% in patients who have undergone pelvic radiation and in reoperations (Montague, 1992). Skin pathogens are the most commonly cultured organism, usually from *Staphylococcus epidermidis* and *Staphylococcus aureus* (Licht et al, 1995; Magera and Elliott, 2008). The introduction of the InhibiZone (American Medical Systems) surface treatment combining rifampin and minocycline hydrochloride to the AUS cuff and pump was postulated to lead to a reduction in postoperative infection rates, although the reduced infection rate seen with penile implants (Carson, 2004) has not been replicated in the AUS literature (de Cógáin and Elliott, 2013). Late infections (>4 months) may represent indolent organisms introduced at the time of infection or by hematogenous spread. Therefore, in men with AUS, antibiotics should be considered before urinary tract manipulation in accordance with AUA Guidelines (Wolf et al, 2008).

The initial presentation of an early postoperative AUS infection is usually scrotal pain, although erythema, edema, and frank purulence will commonly accompany this symptom. Because implant infections are not amenable to antibiotic therapy, AUS infection will almost always require explantation. Traditional management includes device removal followed by a waiting period of several months with delayed reimplantation.

Immediate salvage of infected, noneroded AUS can be accomplished with complete device removal, antiseptic irrigation, and immediate reimplantation (Kowalczyk et al, 1996b; Bryan et al, 2002). This procedure includes an irrigation regimen used in penile prosthesis salvage protocols (Mulcahy et al, 1995). Mulcahy and associates used this approach to salvage seven of eight patients with infected noneroded AUS in a total of nine operations (Bryan et al, 2002). In all cases the entire AUS was removed and the wounds were copiously irrigated according to a seven-solution protocol before a new system was implanted. Contraindications to prosthesis

salvage include sepsis, ketoacidosis, necrotizing infection, immunosuppression, and the finding of gross purulent material at the time of explantation.

Urethral Erosion

Urethral erosion is reported in up to 5% of AUS implantations (Gundian et al, 1989; Marks and Light, 1989; Litwiller et al, 1996; Singh and Thomas, 1996; Montague and Angermeier, 2000). Furlow and Barrett (1985) introduced the concept of postoperative deactivation during the healing process to decrease pressure-induced ischemia and necrosis. Delayed deactivation has lowered the risk for urethral erosion, especially in cases of reimplantation. Motley and Barrett (1990) saw a decrease in secondary urethral erosion from 18% to 1.3% with this technique. In an analysis of their 13-year experience in patients with urethral erosions, Webster and associates (Raj et al, 2006) determined that patients with hypertension, coronary artery disease, prior radiation therapy, and prior AUS revisions were more than twice as likely to suffer secondary urethral erosions.

Immediate removal of all the components of the AUS is imperative in cases of erosion, because they are assumed to be infected. The urethral injury is managed with urethral catheter drainage and/or suprapubic cystostomy (Kowalczyk et al, 1996b; Flynn and Webster, 2004). Perineal wounds are considered infected and loosely approximated or allowed to close by secondary intention. Reimplantation is considered only after urethral healing is confirmed by urethrography and a delay of 3 to 6 months is observed.

Urethral patency must be confirmed by cystoscopy or retrograde urethrogram before attempted device replacement (Motley and Barrett, 1990; Kowalczyk et al, 1996b; Frank et al, 2000). A new cuff should be placed either proximal or distal to the previous site. Significant scarring as well as a compromised vascular supply makes replacement of the cuff at the erosion site difficult and risky (Motley and Barrett, 1990; Kowalczyk et al, 1996b). Frank and colleagues (Frank et al, 2000) reported a successful outcome in 87% of de novo reimplantations after erosion or infection, with recurrent urethral erosion in 8.7%. The authors recommended nightly deactivation of the AUS in cases of reimplantation for prior erosion. More recently, in a series of 46 patients with prior AUS erosion who underwent reimplantation, 35% suffered another erosion within an average of 6.7 months (Raj et al, 2006). Use of the transcorporeal approach in such cases may reduce the risk for urethral injury during the secondary surgery as well as potentially provide greater protection against subsequent erosion.

Urethral Atrophy

Urethral atrophy results from the chronic compression of the spongy tissue under the occlusive cuff. This is the most common reason for revision of the AUS. Treatment options include cuff downsizing, movement of the cuff to a more proximal or distal location where the urethra may be thicker, or placement of a second cuff in tandem. Simple replacement of the PRB with a higher pressure reservoir to overcome urethral atrophy is no longer recommended because of the risk for erosion (Raj et al, 2005).

Our approach is to downsize the cuff in the same location when possible. If the existing cuff is 4.0 cm, the option to use a 3.5-cm cuff is now available. Alternatively, we reposition the cuff more proximally, when feasible, or distally using the transcorporeal technique if necessary, and measure the appropriate cuff size. Saffarian and associates (2003) reported a significant improvement in daily pad usage from 3.9 to 0.5 in 17 patients with urethral atrophy. In a large series of secondary AUS surgery, the cuff was replaced in 142 cases, of which 33% of cuffs were placed distal to the original location, 11% were placed proximal, and 52% were placed at the original cuff location (Raj et al, 2005). The cuffs were downsized in 56% of cases, unchanged in 30%, and upsized in 13%, reflecting the new locations. In cases of urethral atrophy, several prominent centers have successfully added a second cuff in tandem to salvage continence (Brito et al, 1993; DiMarco and Elliott, 2003).

Mechanical Failure

The historical incidence of mechanical failure has diminished substantially after introduction of the narrow-backed cuff. [Elliott and Barrett \(1998\)](#) reviewed the long-term durability of the AMS 800 in 323 patients who underwent implantation at the Mayo Clinic between 1983 and 1994. The change in design resulted in a decrease in nonmechanical failure from 17% to 9%, primarily because of a reduction in urethral atrophy. A decrease in mechanical failure from 21% to 7.6% was primarily the result of a reduction in cuff leak, along with improvements in the synthetic material that lessened the risk for fracture or kinking of the device. **Patients can generally expect a 7- to 10-year device life for the AUS. In the absence of infection or erosion, replacement of an isolated malfunctioning component may be feasible if the revision occurs within 3 years of implantation. However, a slow leak from the PRB may be difficult to diagnose intraoperatively, and, if in doubt, total device replacement is prudent. Devices greater than 3 years old should be replaced in toto.**

Special Circumstances

The management of **urethral and vesicourethral anastomotic stricture** encountered after AUS implantation proposes a unique challenge. Stricture at the site of the AUS cuff may result from compression or ischemia and may indicate impending urethral erosion. One such bulbar urethral stricture was successfully managed with periodic filiform and follower dilation ([Debell and Wessells, 2001](#)). Others have successfully treated strictures proximal to an AUS with balloon dilation ([Westney et al, 1999](#)) or holmium laser through a flexible ureteroscope ([Anger et al, 2005](#)). In the event significant endoscopic manipulation is required proximal to the cuff site, our practice is to surgically uncouple the cuff for the duration of the endoscopic procedure.

SLING COMPLICATIONS

The most commonly reported complications of male slings include perineal pain, urinary retention, infection, anchoring complications from bone anchors, and rare cases of erosion. **Perineal pain may be reported in up to 74% of patients after bone-anchored slings, but most resolve within 3 months ([Comiter, 2005](#)).** Retention is short lived and resolves within several weeks. Isolated cases have required release of the sling. The infection/erosion rate for both types of slings ranges from 2% to 15% and the need for revision (secondary to bone-anchor dislodgement) has been reported from 2% to 4.2%. Larger series with longer term follow-up suggest low rates of erosion and infection ([Bauer et al, 2010](#)). Patients should be counseled as to the possibility of persistent pain and osteitis pubis after slings, although such complications are extremely rare.

KEY POINTS: COMPLICATIONS

- Device infection requires total explantation and salvage antibiotic regimens.
- Device erosion requires total explantation and catheter drainage.
- Troubleshooting of recurrent UI after AUS requires a systematic and exhaustive evaluation.
- Cuff atrophy requires downsizing, repositioning, tandem cuff, or transcorporeal surgery.

LONG-TERM RESULTS OF ARTIFICIAL URINARY SPHINCTER AND SLINGS

Outcomes of surgical correction of male UI depend on patient and device characteristics. First in importance is the severity of UI. Many

urologic surgeons reserve sling surgery for mild-to-moderate degrees of incontinence, but severity is poorly characterized by pad number (see earlier). A difference in baseline incontinence between studies introduces unmeasured bias and makes comparisons of case series difficult. We have summarized available data in [Table 91-2](#).

[Montague and Angermeier \(2000\)](#) reviewed the results of the AUS in 286 patients from five centers. They noted that on average 76% of patients were dry (dry zero or one pad per day) and 13% were improved, for an overall success rate of 89% at a mean follow-up of 18 to 44 months. Revision of the device occurred due to urethral erosion in 5%, AUS infection in 3%, and mechanical failure in 15%. Other studies have confirmed these results ([Hajivasiliou, 1999](#); [Venn et al, 2000](#)). Although many patients still need minor protection with urinary pads, most are satisfied with the long-term outcome of the AUS ([Haab et al, 1997](#); [Montague et al, 2001](#); [Dalkin et al, 2003](#)). Success rates for revision surgery compare favorably with initial surgery, although infection and erosion rates are higher ([Raj et al, 2005](#)). Differences among centers may be related to surgical volume, inclusion of secondary implants, and the sensitivity and accuracy of outcome measures. The long-term fate of patients implanted with transcorporeal cuffs and the newly introduced 3.5-cm cuff remains to be determined. Initial results from one center are promising ([Hudak and Morey, 2011](#)), although outcomes from other centers presented in abstract form ([Voelzke, 2013](#)) raise a note of caution regarding infection and erosion, likely a result of the complexity of cases in which the urethra is narrowed as a result of prior surgery, erosion, radiation, or other causes ([Lai and Boone, 2012](#)).

Results with the bone-anchored and transobturator sling appear similar to those with AUS (see [Table 91-2](#)). Initial success rates with both devices were very high, although subsequent series show greater variability of outcomes ([Guimaraes et al, 2009](#)). One surgeon did not identify a learning curve in adoption of the transobturator male sling ([Zuckerman et al, 2013](#)), but other centers with less extensive experience with male urethral surgery, AUS, or female sling surgery may note greater variation in outcomes with initial cases.

The role of the transobturator AdVance sling in the armamentarium has been firmly established. Early promising results ([Bauer et al, 2009](#); [Soljanik et al, 2012](#)) have been confirmed by other centers, and a persistent benefit with only modest deterioration of outcome at 2 to 3 years of follow-up has been reported ([Bale, 2011](#); [Bauer et al, 2011](#); [Li et al, 2012](#); [Rehder et al, 2012](#); [Kowalik et al, 2015](#)). Patient selection criteria are evolving, particularly with regard to cutoffs based on incontinence severity (e.g., pad number or weight) for consideration of AUS. The poorer prognosis for patients having undergone prior adjuvant radiotherapy has been replicated in additional series ([Torrey et al, 2013](#)).

The approach to failure of the male sling is also evolving. Reoperation and implantation of AUS has been shown to be safe and effective after a prior male sling, having similar outcomes as in surgically naive patients ([Lentz et al, 2012](#); [Linder et al, 2013](#)). Repeat male sling surgery was effective in one study, with the caveat that selection criteria must be carefully considered ([Soljanik et al, 2010](#)).

The inconsistent outcomes with male perineal sling surgery likely also reflect variability in rhabdosphincter function. In the future, quantitative assessment of residual rhabdosphincter function may be important in selection of patients for sling surgery or AUS. Finally, sling implantation inherently introduces greater variability in technique. Many factors are at play, including location of sling placement along the bulbar urethra, pelvic bony anatomy, degree of tension placed on the device, and other unmeasured influences. In contrast, the AUS occludes the bulbar urethra with a very high degree of reproducibility and mechanical reliability, allowing consistent results regardless of the degree of incontinence or experience of the surgeon.

SUMMARY

The continued high rate of surgery for localized prostate cancer portends that male sphincteric UI will remain prevalent and require

KEY POINTS: LONG-TERM RESULTS OF ARTIFICIAL URINARY SPHINCTER AND SLINGS

- AUS continues to provide a reliable solution to male UI of all degrees of severity across the range of first-time implantation to complex reoperative and high-risk patients.
- Transobturator slings such as Advance and newer devices provide long-term durable outcomes for mild-to-moderate male UI after radical prostatectomy.
- Bone-anchored sling demonstrates high rates of success, but the most commonly used InVance sling is no longer commercially available in the United States.

surgical treatment to improve symptoms and quality of life. The initial evaluation must include a focused history and physical examination, voiding diary, pad weight test, and, in selected cases, cystoscopy and pressure-flow urodynamics. The AUS remains the gold standard treatment for moderate-to-severe male UI, especially in complex cases, with excellent overall success and acceptable complication rates. For mild-to-moderate UI in the absence of prior urethral surgery, radiation therapy, or detrusor acontractility, male slings provide efficacious alternatives. The outcomes after AUS and male sling cannot be fully compared because of differences in baseline incontinence severity, end points, follow-up, and patient numbers. Nevertheless, **regardless of severity, nearly 90% of men with sphincteric UI will have minimal leakage and acceptable quality of life related to urinary symptoms after surgical treatment.** Similar cured and improved rates for UI after radical prostatectomy have been reported with both the bone-anchored and transobturator slings. However, several caveats exist. Results of slings in radiated patients are inferior. The appropriateness of standard transobturator slings for incontinence of other causes (e.g., TURP, neurogenic, post-traumatic) has not been demonstrated. No sling has been compared to AUS in a controlled clinical trial. It is

likely that selection bias regarding UI severity and other factors exists in choosing a sling versus AUS at most institutions. Furthermore, **perineal sling implantation depends on subtle technical maneuvers relating to positioning and tensioning.** Conversely, **once the urethra has been circumferentially mobilized and measured, the effectiveness of AUS is largely independent of technique.** Thus, the occasional implanter will be more likely to achieve success with AUS versus sling procedures, although the potential for erosion and mechanical failure will continue to drive the need for alternative solutions.

Tumors of the Bladder

David P. Wood, Jr., MD

Benign Tumors of the Bladder

Urothelial Cancer

The urothelium of the bladder is traditionally considered to be lined by transitional cells, which, as suggested by the name, can transform into a variety of benign and malignant tumors. In this chapter we will discuss the epidemiology, etiology, pathology, staging, origin, recurrence, dissemination, molecular biology, detection, and prevention of the more common benign and malignant tumors of the bladder, with an emphasis on urothelial cancer.

BENIGN TUMORS OF THE BLADDER

There are numerous benign tumors of the bladder, but the more common ones include epithelial metaplasia, leukoplakia, inverted papilloma, nephrogenic adenoma, leiomyoma, cystitis cystica, and cystitis glandularis.

Epithelial Metaplasia

Epithelial metaplasia is focal areas of transformed urothelium with normal nuclear and cellular architecture surrounded by normal urothelium usually located on the trigone and composed of squamous (squamous metaplasia) or glandular (glandular metaplasia) cells. Squamous metaplasia often has a knobby appearance and is covered by white, flaky, easily disrupted material lying on the trigone. Glandular metaplasia appears as clumps of raised red areas that appear inflammatory and are often confused for cancer. Approximately 40% of women and 5% of men have squamous metaplasia of the bladder, which is usually related to infection, trauma, or surgery (Ozbey et al, 1999). Spinal cord injury is associated with squamous metaplasia, most likely from catheter trauma and urinary tract infections (Vaidyanathan et al, 2003). Glandular metaplasia can extensively involve the bladder, particularly the trigone, but biopsy is not required. Treatment is unnecessary, and a preventive agent has not been identified.

Leukoplakia

Leukoplakia of the bladder is similar to squamous metaplasia with the addition of keratin deposition that appears as a white flaky substance floating in the bladder (Staack et al, 2006). Leukoplakia occurs in other organs that are covered by squamous epithelium and is often premalignant (Zhang et al, 2009). However, cytogenetic studies on bladder leukoplakia are consistent with a benign lesion, and no treatment is necessary (Staack et al, 2006).

Nonurothelial Malignancies

Inverted Papilloma

An inverted papilloma is a benign proliferative lesion that is associated with chronic inflammation or bladder outlet obstruction and can be located throughout the bladder but most commonly on the trigone, comprising less than 1% of all bladder tumors (Jones et al, 2007; Kilciler et al, 2008; Picozzi et al, 2012). Inverted papillomas demonstrate an inverted growth pattern composed of anastomosing islands of histologically and cytologically normal urothelial cells invaginating from the surface urothelium into the lamina propria but not into the muscularis propria (Fig. 92-1) (Picozzi et al, 2012). When diagnosed according to strictly defined criteria (e.g., lack of cytologic atypia), inverted papillomas behave in a benign fashion with only a 1% incidence of tumor recurrence (Kilciler et al, 2008; Picozzi et al, 2012). The use of fluorescence in situ hybridization (FISH) to evaluate chromosomal changes can distinguish between an inverted papilloma and a urothelial cancer with an inverted growth pattern (Jones et al, 2007). Transurethral resection is the treatment of choice.

Papilloma

Urothelial papilloma is a benign proliferative growth in the bladder that is composed of delicate stalks lined by normal-appearing urothelium (see Fig 92-1) (Montironi and Lopez-Beltran, 2005). Papillomas had previously been categorized as grade 1 Ta tumors of the bladder until the World Health Organization (WHO) changed the classification of noninvasive bladder cancer in 1998 (Epstein et al, 1998). Papillomas rarely have mitotic figures and lack markers of aggressive growth such as TP53 or RB mutations, but 75% of these tumors have mutations in fibroblast growth factor receptor-3 (FGFR-3) (van Rhijn et al, 2004). Papillomas may recur, but they do not progress or invade.

Nephrogenic Adenoma

Nephrogenic adenoma is a rare tumor caused by chronic irritation of the urothelium; it arises from a variety of sources, including trauma, previous surgery, renal transplantation, intravesical chemotherapy, stones, catheters, and infection (Wood et al, 1988; Pavlidakey et al, 2010). Nephrogenic adenoma is composed of glandular-appearing tubules similar to renal tubules that involve the mucosa and submucosa of the bladder. The lesion may be vascular, which explains the presence of gross hematuria in most cases (Franke et al, 2011). There is no racial or gender association with the entity. The constant theme of chronic inflammation

Figure 92-1. Papilloma.

Figure 92-2. Cystitis glandularis.

suggests that metaplastic changes to the urothelium lead to nephrogenic adenoma, although some authors have proposed a theory that nephrogenic adenoma arises from nests of displaced mesonephric tissue in the urothelium that is activated with mucosal injury (Franke et al, 2011). The most frequent presenting sign is gross hematuria, often in conjunction with a urinary tract infection. Treatment consists of transurethral resection and elimination of the chronic irritation.

Cystitis Cystica and Glandularis

Cystitis cystica and/or glandularis is a common finding in normal bladders, usually associated with inflammation or chronic obstruction (Semins and Schoenberg, 2007). These benign tumors represent cystic nests that are lined by columnar or cuboidal cells and are typically associated with proliferation of von Brunn nests (Fig. 92-2). Cystitis glandularis can be associated with pelvic lipomatosis and may occupy the majority of the bladder (Buckley et al, 2007). There have been a few case reports of cystitis cystica or glandularis transforming into adenocarcinoma, and therefore regular endoscopic evaluation of patients with these entities is recommended (Smith et al, 2008). The most common presenting feature of cystitis cystica or glandularis is irritative voiding symptoms and hematuria. Treatment is transurethral resection and relief of the obstruction or inflammatory condition.

Leiomyoma

Leiomyomas are the most common nonepithelial benign tumor of the bladder composed of benign smooth muscle. Several hundred cases have been reported, but this may under-represent the true prevalence. These tumors occur most commonly in women of child-bearing age and are histologically similar to leiomyomas of the uterus (Goel and Thupili, 2013). Leiomyomas appear as smooth indentations of the bladder and can be confused with a bladder tumor except for the normal urothelium overlying the tumor (Fasih et al, 2008). Imaging, especially magnetic resonance imaging (MRI), can confirm the diagnosis and spare invasive procedures (Fasih et al, 2008). Surgical resection is required if the leiomyoma is large or painful.

UROTHELIAL CANCER

Epidemiology

The incidence rate of a cancer is defined as the number of new cancers diagnosed per 100,000 persons per year. The prevalence rate is the total number of cancers per 100,000 persons per year, not just new cases. Because urothelial cancer is a cancer of the environment and age, the incidence and prevalence rates increase with age, peaking in the eighth decade of life, and there is a strong association between environmental toxins and urothelial cancer formation (Parkin, 2008; Siegel et al, 2013). The incidence rate of urothelial cancer has been rising over the last 60 to 70 years, but the rate of rise has recently decreased significantly and in some geographic areas has leveled off (Parkin, 2008). Unfortunately, the incidence rate is rising the fastest in underdeveloped countries where industrialization has led to carcinogenic exposure.

According to the latest American Cancer Society statistics, there were 72,570 total cases diagnosed in the United States in 2013 involving 54,610 men and 17,960 women and accounting for 7% of all cancers (Siegel et al, 2013). Bladder cancer is a lethal disease, with 15,210 deaths recorded in 2013, including 10,820 men and 4390 women, and accounts for 3% of all cancer deaths (Siegel et al, 2013). Bladder cancer contributes to 0.7% of the absolute decrease in the cancer death rate seen during this time, when all cancers are considered (Siegel et al, 2013). Globally, the incidence rate of bladder cancer has been increasing, but because of smoking cessation programs, at a slower rate over the last decade (Parkin, 2008). The mortality rate from bladder cancer has decreased significantly from 1990 to 2004, with both men and women achieving an 18.4% decrease in mortality rate (Fig. 92-3). This decrease in mortality rate is more striking in men than women because of the earlier peak when men began to smoke, which occurred approximately 20 years before women. Because of the latency period with urothelial cancer-causing agents in tobacco, we should see a commensurate decrease in the mortality rate in women in 15 to 20 years as their smoking cessation programs become more widespread.

Gender, Racial, and Age Differences

Males are 3 to 4 times more likely to develop bladder cancer than females, presumably because of an increased prevalence of smoking and exposure to environmental toxins (Parkin, 2008; Siegel et al, 2013). African-American males have a 19% higher incidence rate than white males for all cancers and a 37% higher death rate. However, for urothelial cancer, white males have a higher incidence and death rate than African-Americans (Parkin, 2008; Siegel et al, 2013). African-American women have a 6% lower incidence but a 17% higher death rate than white women for all cancers (Siegel et al, 2013). However, bladder cancer is roughly 1.5 times more common in white women than in African-American women. A white male has a 3.7% chance of developing urothelial cancer in his lifetime, which is roughly 3 times the probability for white females or African-American males and more than 4.5 times the probability for African-American females (Hayat et al, 2007; Siegel et al, 2013). The risk of developing invasive bladder cancer

Figure 92-3. Age-standardized rate (ASR) of global mortality from bladder cancer. (From Parkin DM. The global burden of urinary bladder cancer. *Scand J Urol Nephrol Suppl* 2008;218:12–20.)

is age dependent (Siegel et al, 2013). For men from birth to age 39 years, the incidence rate of invasive bladder cancer is 0.02%; ages 40 to 59 years, 0.41%; ages 60 to 69 years, 0.96%; ages 70 years and older, 3.5%; and from birth to death, 3.7%. The bladder cancer incidence for women from birth to age 39 years is 0.1%; ages 40 to 59 years, 0.13%; ages 60 to 69 years, 0.26%; ages 70 years and older, 0.99%; and from birth to death, 1.17%. In general, adolescents and young adults (younger than 40 years) tend to develop well-differentiated noninvasive, rather than invasive, bladder cancer (Linn et al, 1998). Unlike many other cancers in which younger patients tend to develop more aggressive disease, the opposite appears to be true in bladder cancer, because these patients more frequently have noninvasive low-grade tumors at presentation (Wang et al, 2012b).

Global Burden of Bladder Cancer
